Abstract. An analysis of the 22-yr ozone (O_3) series (1988–2009) at the subtropical high mountain Izaña station (IZO; 2373 m a.s.l.), representative of free troposphere (FT) conditions, is presented. Diurnal and seasonal O_3 variations as well as the O_3 trend ($0.19 \pm 0.05 \text{ \% yr}^{-1}$ or $0.09 \text{ ppbv yr}^{-1}$), are assessed. A climatology of O_3 transport pathways using backward trajectories shows that higher O_3 values are associated with air masses travelling above 4 km altitude from North America and North Atlantic Ocean, while low O_3 is transported from the Saharan continental boundary layer (CBL). O_3 data have been compared with PM_{10} , ^{210}Pb , ^7Be , potential vorticity (PV) and carbon monoxide (CO). A clear negative logarithmic relationship was observed between PM_{10} and surface O_3 for all seasons. A similar relationship was found between O_3 and ^{210}Pb . The highest daily O_3 values (90th percentile) are observed in spring and in the first half of summer time. A positive correlation between O_3 and PV, and between O_3 and ^7Be is found throughout the year, indicating that relatively high surface O_3 values at IZO originate from the middle and upper troposphere. We find a good correlation between O_3 and CO in winter, supporting the hypothesis of long-range transport of photochemically generated O_3 from North America. Aged air masses, in combination with sporadic inputs from the upper troposphere, are observed in spring, summer and autumn. In summer time high O_3 values seem to be the result of stratosphere-to-troposphere (STT) exchange processes in regions neighbouring the Canary Islands. Since 1995–1996, the North Atlantic Oscillation has changed from a predominantly high positive phase to al-

ternating between negative, neutral or positive phases. This change results in an increased flow of the westerlies in the mid-latitude and subtropical North Atlantic, thus favouring the transport of O_3 and its precursors from North America, and a higher frequency of storms over North Atlantic, with a likely higher incidence of STT processes in mid-latitudes. These processes lead to an increase of tropospheric O_3 in the subtropical North Atlantic region after 1996 that has been reflected in surface O_3 records at IZO.

1 Introduction

Ozone (O_3) is an important trace gas in the troposphere (Fishman and Crutzen, 1978). It affects the oxidizing capacity of the troposphere (Levy, 1971; Logan, 1985; Thompson, 1992), it is a phytotoxicant that can affect public health (Tiao et al., 1975), and is an important greenhouse gas (Ramanathan et al., 1985; Mitchel, 1989). A portion of the O_3 is downward transported from the stratosphere (Junge, 1962; Danielsen, 1968; Levy et al., 1985), while most of the tropospheric O_3 is believed to be produced in the troposphere itself by photochemical reactions involving nitrogen oxides (NO_x) and carbon monoxide (CO) (Lelieveld and Dentener, 2000; Jonson et al., 2006). Thus, O_3 concentrations may be viewed as the sum of a global/hemispheric background concentration and regionally/locally produced O_3 (Jonson et al., 2006).

Results from Graustein and Turekian (1996) indicate an upper troposphere source for elevated O₃ in summer time subtropical free troposphere (FT) of the eastern North Atlantic, and James et al. (2003) found evidence of deep stratospheric intrusions down to the lower FT over the Canaries even in summer. Oltmans et al. (1996) reported evidence of high O₃ concentration (~ 100 ppb) layers in the middle and upper troposphere over the North Atlantic which are invariably associated with transport characteristics that strongly support a stratospheric source for these layers.

However, other authors (e.g. Moody et al., 1996; Creilson et al., 2003; Hegarty et al., 2009) suggest that a substantial amount of photochemically generated tropospheric O₃ is transported from continental source regions over the North Atlantic. Some studies have revealed the great impact of this pollution over the air quality of Europe (e.g. Parrish et al., 1993; Li et al., 2002a; Prather et al., 2003). As pointed out by Stohl (2001) and Stohl et al. (2002), the long-range transport of O₃ from North America to Europe is more efficient in the middle and upper FT because the westerlies are stronger than in the marine boundary layer (MBL), and also because of a longer O₃ lifetime. Val Martin et al. (2008) suggest that a substantial amount of additional O₃ formation occurs in the anthropogenic plumes during transport to the central North Atlantic lower FT.

Assessment of long-term trends in tropospheric O₃ is difficult due to the scarcity of representative observing sites with long records (Solomon et al., 2007). In addition, the long-term tropospheric O₃ trends vary both in terms of sign and magnitude and in the possible causes of the change (Oltmans et al., 2006). Some O₃ trends have been attributed to changes in O₃ precursor emissions (Scheel, 1983). However, further studies reveal that O₃ trends cannot be fully explained based on its precursors alone. For example, Staehelin and Poberaj (2008) argue that further increase in background O₃ over Europe and North America since the early 1990s cannot be solely explained by regional O₃ precursor changes because anthropogenic O₃ precursor emissions were drastically reduced in the industrialized countries as a consequence of air quality legislation. Gilge et al. (2010) also state the apparent contradiction between the rather constant O₃ concentrations observed at ground stations during the end of the 1990s to 2007 and the substantial reductions in anthropogenic emissions. The surface O₃ positive trend found at elevated European sites was explained by Ordóñez et al. (2007) in terms of an increased contribution of stratospheric O₃ in the 90s. Conversely, Tarasova et al. (2003) found negative trends in a high mountain in Russia, and Vingarzan (2004) and Tarasova et al. (2009) reported a slower rate of tropospheric O₃ increase or in some cases lack of an increase over the past decade. Logan et al. (2012) found a slow decrease in summer surface ozone in alpine stations and in the free troposphere over Europe, with an average trend of -0.15 ppb yr⁻¹ since 1998. Spatial and temporal evolution of atmospheric processes driving O₃ concentrations affect stations located in different regions of

the world in different ways, as it has been recently reported by Oltmans et al. (2013). In this regard Jonson et al. (2006) address the question if the observed O₃ trends can be understood.

Model simulations suggest that the increase of background tropospheric O₃ observed in mountain tops can be only partially explained by changes in emissions of precursors over continents, and may be affected by changes in the circulation of the troposphere (Jonson et al., 2006). For example, Appenzeller et al. (2000) found a good correlation between the North Atlantic Oscillation (NAO) index and column tropospheric O₃ over the eastern North Atlantic, and Eckhardt et al. (2003) demonstrated how the NAO controls the air pollution transport to the Arctic. Duncan and Bey (2004) explained that the CO burden from Europe tended to be higher over the North Atlantic and lower over the Arctic when the NAO was in the negative phase. So, reductions in O₃ caused by reductions in precursors may be masked by periodical changes in atmospheric circulation. As noted by Jonson et al. (2006), the changes suffered by the stratospheric O₃ in the last decades could alter the circulation patterns, which would affect, in turn, the exchange between the stratosphere and troposphere.

Most of the studies address the origin of tropospheric ozone from only one of the most common approaches: photochemistry or atmospheric dynamics, which is a limited and partial view of the driving forces. Therefore, we propose, firstly, a detailed analysis of a long-term (22 yr) surface O₃ time series (1988–2009) at the Izaña high mountain station (hereafter IZO), which is representative of background conditions of the lower troposphere in the subtropical North Atlantic region, where there is very little information available. Secondly, we present an extensive and multidisciplinary review of the O₃ transport processes into the FT of the North Atlantic subtropical region, incorporating other components such as particulate matter, CO, ⁷Be, ²¹⁰Pb, and additional information from backward trajectories, potential vorticity (PV), and the NAO index.

The surface O₃ measurement programme of IZO is run with an independent quality assurance system, within the World Meteorological Organization (WMO) Global Atmospheric Watch (GAW) Programme, which precludes data biases and prevents wrong interpretations in trends analysis. Our paper is structured as follows: data and methods are described in Sect. 2. In Sect. 3 a surface O₃ climatology and transport pathways characterization is presented, and a discussion about surface O₃ observations, their relationships with other atmospheric components (PM₁₀, ²¹⁰Pb, PV, ⁷Be, and CO), and their connections with synoptic-scale dynamical processes driven by the NAO is given. In Sect. 4 a summary and main conclusions are provided.

2 Data and methods

2.1 Measurement site

The Izaña GAW Observatory is located at 28.3° N, 16.5° W at an altitude of 2373 m a.s.l. (annual mean pressure of ~770 hPa) on Tenerife Island, (Canary Islands, Spain) on top of a mountain platform on a dorsal ridge which crosses the island from SW to NE. A belt of endemic pine forest (*Pinus Canariensis* Chr, Sm. Ex DC) grows between 600 and 2000 m a.s.l., whereas at higher levels there is only a sparse cover of local species of broom (*Spartocytisus supranubius*) growing on lava terrain. Except for a few scattered residences, Tenerife is uninhabited above the 1000 m level. The horizontal distances from IZO to the north-west and to the south-east coasts (the direction of the prevailing winds) are less than 15 km. The nearest distance to the European continent is 1300 km and about 350 km to Africa.

2.2 In situ surface O₃ instrumentation

The surface O₃ monitoring programme at IZO started in May 1987 using a UV absorption technique. The analysers used in different periods from this time up to the present, as well as the reference instruments and the quality assurance programmes are specified in Table 1. The terminology used in Table 1 is the following:

- Basic instrument: analyser from which the final data result.
- Backup instrument: instrument that is monitoring in parallel to the basic analyser.
- Reference instrument: analyser for independent comparisons and calibrations (not used for ambient air measurements).

O₃ has been measured continuously recording 10-min averages with the corresponding standard deviation from May 1987 to July 1996. After this date, and up to now, 1-min average O₃ values with corresponding standard deviations are recorded for both the basic and the backup instruments. Zero-checks with an activated-carbon absorber were performed on a daily basis to detect instrumental offset drifts. Surface O₃ data at IZO have been also calibrated against references that are traceable to NIST (US National Institute for Standards and Technology) reference O₃ photometer (Gaithersburg, Maryland, USA). The Izaña surface O₃ programme has been audited by the World Calibration Centre for Surface Ozone, Carbon Monoxide and Methane (WCC-Ozone-CO-CH₄-EMPA) in 1996, 1998, 2000, 2004 and 2009. EMPA's audit reports are available at http://www.empa.ch/gaw/audits/IZO_yyyy.pdf, where yyyy is the year. The audits were performed according to the “Standard Operating Procedure (SOP) for performance auditing O₃ analysers at global and regional WMO-GAW sites”, WMO-GAW Report No. 97. All audited field instruments (basic

and backup instruments) fulfilled the assessment criteria as “good” over the tested range up to 100 ppbv.

2.3 Backward trajectories, O₃ MCAR plots, residence times, and BTMH plots

Five-day HYSPLIT (Hybrid Single-Particle Lagrangian Integrated Trajectory) version 4.0 dispersion model backward trajectories (Draxler and Rolph, 2003; Rolph, 1983) with a time resolution of 1h were calculated using the FNL (Final Analysis Data) meteorological dataset (from May 1987 to December 2004) and the GDAS (Global Data Assimilation System) meteorological dataset (from January 2004 to December 2009), both from the National Centres for Environmental Prediction. The vertical component of the backward trajectories was computed using the vertical model velocity. The end point was set at Tenerife (28.3° N, 16.5° W) at 2400 m a.s.l. (IZO height) for each day of the study period (1 January 1988–31 December 2009) at 00:00 UTC.

The transport paths of the air masses reaching Tenerife (00:00 UTC) have been characterized using the permanence indices for the predefined source geographic sectors described in Alonso-Pérez et al. (2007) and summarized in Table 2. Permanence indexes were calculated as the fraction of time that an air mass trajectory calculated for 120 h resides in a predefined particular geographic sector and also in a predefined altitude range. We consider “low” an altitude range between surface level and 1.5 km, “medium” an altitude range between 1.5 and 3 km, and “high” > 3 km (normally with a top height at 6 km). Permanence indexes were obtained using 5-day HYSPLIT backward trajectories.

Source–receptor relationships of atmospheric composition can be investigated with backward trajectory techniques, tracing forward from a defined geographical origin to arrive at measurement sites where the composition may have altered during transport (Fleming et al., 2012). One of these techniques is the so-called “mean concentrations at receptor” (MCAR). For each pixel of our geographical domain, we select the backward trajectories which arrive at IZO and pass over that pixel. The daily mean O₃ concentrations measured at Izaña on the corresponding trajectory arrival days are averaged, and this average is plotted on that pixel. MCAR plots allowed the identification of pathway regions with high and low O₃. The methodology has been described by Rodríguez et al. (2011). Monthly MCAR plots of surface O₃ were determined using daily 5-day backward trajectories calculated at 00:00 UTC and daily (nocturnal) surface O₃ data at IZO for the period 1988–2009.

The identification of the transport corridors and source regions of O₃ was complemented by using the residence time analysis technique (Poirot and Wishinski, 1986). For this issue, the geophysical region covered by the trajectories was divided into 408 grid cells of 5° × 5° (latitude/longitude). The problem with this method is that all of the backward trajectories begin at the receptor site, and thus the residence time

Table 1. Description of O₃ analysers, associated quality assurance, and data acquisition system used during the period 1988–2009. Ri = Reference instrument; Bi = Basic instrument; Bp = Backup instrument; MPC = Multipoint calibration.

Table 2. Geographical sectors used in the backward trajectory classification (function of the continental source regions and oceanic sectors, latitude and longitude ranges).

Sector	Latitude Range	Longitude Range
North America	30–90° N	50–135° W
North Atlantic	30–90° N	10.5–70° W
North Europe	50–90° N	10.5° W–50° E
South Europe	36–50° N	10.5° W–50° E
Sahara	20–36° N	18° W–50° E
Sahel	0–20° N	18° W–50° E
Subtropical North Atlantic	0–30° N	18–135° W
Canary Islands	24.7–31.9° N	12.4–20.6° W

is maximum in the cells surrounding the sampling location (Hopke et al., 2005). We refer to this effect as “central convergence”. We have used a modification proposed by Poirot and Wishinski (1986) to avoid the geometrical “central convergence” effect and highlight the distant O₃ sources.

Backward trajectories have been also used to compute backward trajectory mean height (BTMH) plots. In this case, on each pixel (1° × 1° cell), the mean height at that pixel of the backward trajectories which arrive at IZO and pass over that pixel is plotted.

2.4 Potential vorticity

Potential vorticity (PV; 1 PVU = 10^{−6} m² s^{−1} K kg^{−1}) analysis is a widely used tool to understand the stratosphere-to-troposphere (STT) exchange (e.g. Danielsen, 1968) since PV – the product of absolute vorticity and thermodynamic stability – is greater in the stratosphere than in the troposphere (Hoskins et al., 1985). The dynamical tropopause is typically defined with a PVU value ranging from 1 PVU (Shapiro et al., 1987) to 2 PVU (Appenzeller et al., 1996; Parrish et al., 2000). The dynamical tropopause is defined by (WMO) as the 1.6 PVU iso-surface. This value is used by some authors to identify the signature of stratospheric air (e.g. Stohl et al., 2000; Cristofanelli et al., 2006), while other authors consider two threshold values for the dynamical tropopause – 2 and 1.5 PVU – for deep stratospheric intrusion analysis, as Akritidis et al. (2010). It is assumed that PV > 1 PVU are typical values of tropospheric regions that have been impacted by stratospheric intrusions. Beekman et al. (1994) made use of the positive correlation of PV with O₃ in separating tropospheric O₃ sources on the basis of high and low PV. However, we should note that diabatic heating can reduce the PV values without changing O₃. Thus, PV must be viewed as a bottom indicator of air masses with upper troposphere/lower stratosphere (UTLS) signature.

PV was obtained from ERA-Interim ECMWF (European Centre for Medium-Range Weather Forecasts) reanalysis.

Daily reanalyses at 00:00, 06:00, 12:00 and 18:00 UTC were retrieved at 300, 400, 500, 600, 700, 775, 850 and 925 hPa levels from January 1988 to December 2009 in a regular grid with a spatial resolution of 0.5° latitude/longitude within the geographical domain 20° N–50° W/70° N–30° E.

Maximum PV(PV_{max}) intercepted by daily 5-day backward trajectories for IZO was computed as follows: for each one of the 120 h of the backward trajectory, the PV is calculated by performing a 3-D nearest-neighbour interpolation with the 8-isobaric PV levels of the ECMWF reanalysis. PV was stored for each 1-h point back of the back trajectory. In this work we have used the PV_{max} found along each backward trajectory together with its latitude and longitude.

2.5 ⁷Be and ²¹⁰Pb radiotracers

The ²¹⁰Pb radiotracer (half-life 22 yr) is the decay daughter of ²²²Rn (half-life 3.8 days) which is emitted from soils (Turekian et al., 1977). So, ²¹⁰Pb is a tracer of air masses with continental boundary layer (CBL) signature (Balkanski et al., 1993). The ⁷Be radiotracer (half-life 53.3 days) is produced by cosmic ray spallation reactions with nitrogen and oxygen in the stratosphere and upper troposphere (Viezee and Singh, 1980).

The ⁷Be and ²¹⁰Pb radionuclides were measured at IZO on a daily basis within the AEROCE (AEROSol Ocean chemistry Experiment) project (Prospero et al., 1995) in the period of 1989–1991 as tracers for UTLS and CBL air, respectively.

2.6 Carbon monoxide (CO)

Carbon monoxide (CO) is a good tracer of anthropogenic pollution because it has a relatively long lifetime in the FT, which permits the study of long-range transport. Daily and hourly night-time CO averaged concentrations at IZO, corresponding to the period 2008–2011, have been used for the analysis of long-range transport of photochemical O₃ from polluted regions. CO concentrations have been obtained using an automated TEI 48C-TL (Thermo Electron Corporation) NDIR instrument. The NDIR system was calibrated every 3 months using a 10-ppm CO in N₂ standard from Air Liquide. Automatic zero checks and ambient air measurements are alternated in 15-min intervals to account for short-term drift. A Sofnocat 423 CO scrubber is used for the zero checks. The inlet filter is exchanged every 3 months. One-minute averages including additional instrument status information are stored. The NDIR system has been audited by the WCC-Ozone-CO-CH₄-EMPA in 2009. This audit confirmed the stability and linearity of the instrument, and showed an error of about 10 % when compared to EMPA reference. However, continuous NDIR data have been corrected using discrete NOAA measurements of weekly samples collected in flasks. Consequently, we expect an error lower than 10 %. CO data are used in this work to assess pollution long-range transport by analyzing averaged daily O₃/CO ratios. Thus,

the error associated to CO measurements is acceptable for our purposes.

2.6.1 PM₁₀

Daily nocturnal PM₁₀ (particles less than 10 microns in diameter) concentrations at IZO in the period 2002–2009 have been used for assessing the impact of dust-laden Saharan air masses on O₃ records. The PM₁₀ measurement programme was described by Rodríguez et al. (2011).

2.6.2 North Atlantic Oscillation (NAO) index

The NAO is one of the major teleconnection patterns of the winter Northern Hemisphere (Wallace and Gutzler, 1981), and represents a measure of the strength of the westerlies across the North Atlantic. Monthly mean values of the NAO index have been obtained from NOAA Climate Prediction Center ftp://ftp.cpc.ncep.noaa.gov/wd52dg/data/indices/nao_index.tim. Indices are normalized using the 1981–2010 base period monthly means and standard deviations.

2.6.3 Tropospheric Ozone Residual (TOR)

Tropospheric Ozone Residual (TOR) data are measurements of tropospheric O₃ obtained by subtracting the stratospheric component of O₃ (in the stratospheric aerosol and gas experiment) from the total atmospheric column of O₃ (by use of the Total Ozone Measurement Spectrometer (TOMS) and Solar Backscattered Ultraviolet (SBUV) instruments).

Data over the North Atlantic, northern Africa and Europe within the geographical domain 10° N–30° E/50° N–60° W have been computed from the database available at the following NASA site: <http://asd-www.larc.nasa.gov/TOR/data.html>. A description of the technique can be found in Fishman and Balok (1999) and Fishman et al. (2003).

The TOR seasonal average value for each phase of the NAO within the period 1988–2005 was obtained by averaging for each season the TOR monthly mean values of those months in which NAO > +0.5 (positive NAO) or NAO < –0.5 (negative NAO). Thus, to calculate the TOR mean value corresponding to winter of positive NAO phase, seventeen months of ten years were used; for winter of negative NAO phase, three months of three years; for spring of positive NAO phase, twelve months of nine years; and for spring of negative NAO phase, eleven months of nine years. It should be noted that no TOR data are available in 1994, 1995 and 1996, and in much of the years 1993 and 1997.

3 Results

3.1 Surface O₃ diurnal cycle

Large-scale subsidence, associated to the descending branch of the Hadley cell, is an important meteorological feature of

Fig. 1. Mean diurnal variation of surface O₃ residuals for each month of the year in the period 1988–2009. The O₃ residuals have been calculated on a daily basis as the differences of surface O₃ for every hour compared with the night background level.

the subtropical North Atlantic region. The quasi-permanent NNE trade winds flow over a relatively cold ocean surface that inhibits the development of convection in the MBL and enhances subsidence. A temperature inversion layer (TIL) separates two well-differentiated air masses: the MBL and the FT (Font, 1956). The TIL is characterized by a layer of stratocumulus formed by condensation of water vapour onto the available pre-existing particles. The top of the TIL is generally located around 1200 m a.s.l. in summer, and around 1800 m a.s.l. in winter. IZO normally lies above the TIL that traps local island pollutant emissions. However, under certain synoptic conditions, normally in winter, the TIL reaches the station level or, simply, the TIL is not observed. The effectiveness of the inversion in separating the MBL from the FT at IZO is reflected in the relative humidity typically > 60% below the TIL and ~ 20% above it. Diurnal variations in the altitudes of the bottom (1200 m during daylight and 900 m at night) and the top (1700 m during daylight and 1300 m at night) of the TIL are observed. The influence of buoyant airflows caused by the heating of the air located just above the terrain of the island is observed at IZO. This upslope effect is reflected in the daily cycle of CO₂ concentrations that shows lower values and higher standard deviations during daylight due to uptake by vegetation growing at lower elevations on the slopes (Cuevas et al., 1992). During the night a catabatic air flow regime is well established over the station, favouring the arrival of very clean air masses from higher levels.

The diurnal cycles of O₃ (Fig. 1) were obtained from the differences of O₃ for every hour compared with the night background level. The reference background level has been computed as follows. Firstly, the averages of the pre- (00:00–07:00 h UTC) and post- (21:00–04:00 h UTC) nights were computed. Then, the linear drift in time passing through both averages is used as the reference background level. The use

Fig. 2. Surface O₃ daily night means (black dots), interannual trend (red line) and interannual trend plus annual cycle at IZO from 1988 to 2009.

of a linear drift allows for a background trend. Diurnal cycles of surface O₃ have been averaged for each month using hourly data for the entire period 1988–2009.

Surface O₃ diurnal variations show the lowest values during the afternoon due to an efficient dry deposition on very rough and dark volcanic mountain slopes covered with scattered bushes. This diurnal cycle is the opposite to that recorded in continental regions where a maximum during daylight is observed due to the photochemical production (e.g. Millán et al., 1997). The monthly mean difference between the daily upslope and the nocturnal downslope surface O₃ values is within 2 ppbv in winter and autumn. However, in summer and spring day/night differences are normally above 2 ppbv, being somewhat greater than 5 ppbv in June, and reaching up to 25 ppbv in some days. The amplitude and width of the diurnal O₃ “valley” is basically modulated by two factors: the solar radiation and the consequent heating of the slopes surrounding the observatory, and the strength of the synoptic wind. In winter time the heating of the slopes is minimal, and the strong synoptic winds dilute air masses from lower levels. By contrast, in spring and summer there are the following occurrences: (1) there is a strong warming of the soil (facilitating the mountain breeze); (2) the TIL associated to trade winds is recorded at its lowest level (around 800–1100 m a.s.l.), so the air flows from lower levels, where O₃ concentration is lower, and with a longer path available for dry deposition; and (3) the synoptic winds are usually very weak, resulting in a lower dilution of upslope air. The “ozone valley” in the daytime is a feature also observed in other high mountain stations: Mauna Loa (Oltmans and Levy II, 1994), and Jungfraujoch (Schuepbach et al., 2001).

3.2 Annual and seasonal variations of surface O₃

Daily nocturnal (22:00–06:00 UTC) O₃ values – representative of subtropical FT conditions – have been analyzed for the entire record (1988–2009) using decomposition in three terms: interannual trend, annual cycle, and residual. A least squares fit of the daily data to the function

$$f(t) = a_1 + a_2t + a_3t^2 + \sum_{i=1}^p [b_i \cos(w_i t) + c_i \sin(w_i t)] + \sum_{j=1}^4 [d_j \cos(k_j t) + e_j \sin(k_j t)],$$

has been performed, where t is the time in days ($t = 1$ for 1 January 1988), a_1 , a_2 , a_3 , b_i and c_i are the parameters of the interannual trend to be determined, $p = 7$, d_j and e_j are the parameters of the annual cycle (which is assumed constant) to be determined, $w_i = 2\pi i/N$ with N equal to the number of days in the period 1988–2009 ($N = 8036$, number of valid data = 7790), and $k_j = 2\pi j/T$ with $T = 365.25$ days. See Gómez-Peláez et al. (2006) for a detailed interpretation of this function. Note that in this work we have added a quadratic term in time, following Gómez-Peláez et al. (2010), in order to allow a non-periodic growth rate.

Figure 2 shows the interannual trend and the interannual trend + annual cycle. The average yearly mean O₃ value at IZO for the 22 yr period is 46.1 ppbv. The corresponding standard deviation of the mean is 0.12 ppbv. The root mean square of the residuals is 8.9 ppbv, and the peak-to-peak annual cycle amplitude is 15.4 ppbv. The O₃ increase observed between 1996 and 1998 is striking. There is a slight positive trend in the annual mean (0.09 ± 0.02 ppbv yr^{−1} or 0.19 ± 0.05 % yr^{−1}) that is slightly lower than at Mauna Loa (0.37 ± 0.26 % yr^{−1}, Oltmans and Levy II, 1992). In European alpine stations such as Sonnblick, Jungfraujoch, Hohenpeissenberg and Zugspitze trends are observed in the 0.1–0.4 % yr^{−1} range (Gilge et al., 2010). Over some European stations (Hohenpeissenberg, Zugspitze and Mace Head) small trends or reductions during summer are observed, while there is an increase during winter (Oltmans et al., 2006). Mace Head, a site that is representative of O₃ changes in the air advected from the North Atlantic to Europe in the MBL, has shown a positive trend of 0.16 ± 0.04 ppbv yr^{−1} over the entire period 1988–2007, but this positive trend has reduced during recent years (Tripathi et al., 2010). Hence, tropospheric O₃ trends over Europe do not show a homogeneous behaviour.

Long-term O₃ series should be analyzed by seasons since the processes of transport/production of surface O₃ and its precursors can be very different in each season. In Fig. 3 we have plotted the long-term surface O₃ P10th, P25th, P50th, P75th and P90th (1988–2009) for winter, spring, summer and autumn. P_n th is the n -percentile. In winter a change (increase) in all percentiles is observed in 1997 with a maximum in 1999. A similar behaviour is found in spring, but only in

P50th, P75th and P90th with maximum values in 1998. The lower percentiles do not show significant changes. In summer the increase is smoothed, being only evident in higher percentiles (P75th and P90th). In autumn the change is observable from 1996 in percentiles \geq P50th. Changes in percentile data series observed in the period 1996–1998 will be discussed in Sect. 4.

Figure 4a shows non-detrended monthly means for surface O₃ at IZO, Mauna Loa (Oltmans and Levy II, 1994), Zugspitze-Schneefernerhaus (Nienerowski, 2004), Jungfraujoch (Logan et al., 2012), and Sonnblick (Federal Environment Agency Austria). Data from Mauna Loa and the alpine stations have been downloaded from the World Data Centre for Greenhouse Gases (WDCGG; <http://ds.data.jma.go.jp/gmd/wdogg/>). IZO shows characteristics intermediate to those recorded at Mauna Loa and the alpine stations. Rodríguez et al. (2004) compared the O₃ annual course at IZO with that observed at Mauna Loa, noting that in summer O₃ monthly means sharply decrease in the latter, while high O₃ events (daily mean values of 60–70 ppbv) are recorded at IZO. However, the typical continental annual cycle, with a broad spring/summer maximum observed in the alpine stations, is not seen at IZO where the annual cycle peaks in late spring (May–June). This is an indication that IZO is not affected by photochemical production from regional emissions in summer.

The annual course is shifted towards high values ($> P75$ th) in spring, mid-values ($P25$ th $< P_n$ th $< P50$ th) in winter, and low values ($< P25$ th) in autumn time, while summer contributes significantly in both low and high values (Fig. 4b). ND is the number of daily mean surface O₃ data in each percentile range for the total period 1988–2009. O₃ data above P90th are found in spring and summer whereas O₃ levels below P10th are found in late summer and autumn.

3.3 Synoptic climatology of surface O₃: transport pathways

A previous analysis of transport pathways of O₃ at IZO was performed by Rodríguez et al. (2004). In the present work we have incorporated a longer data series and followed a different approach, using the MCAR plots for each month for the entire surface O₃ dataset (Fig. 5). This methodology does not assume a priori geographical areas, and allows us to visualize the regions from which air masses reaching IZO come with different O₃ concentrations. Since at higher altitudes in the troposphere higher concentrations of O₃ are expected, we have calculated the corresponding BTMH plots for each month of the year for the same period (Fig. 6).

Figure 5 shows in winter (January–March) a well-defined pattern with air masses coming from the North Atlantic and North America with a top latitude located at about 60° N. It is also noticeable a latitudinal gradient with higher O₃ values in northern regions. Concerning the height of the backward trajectories (Fig. 6), a similar latitudinal distribution to the

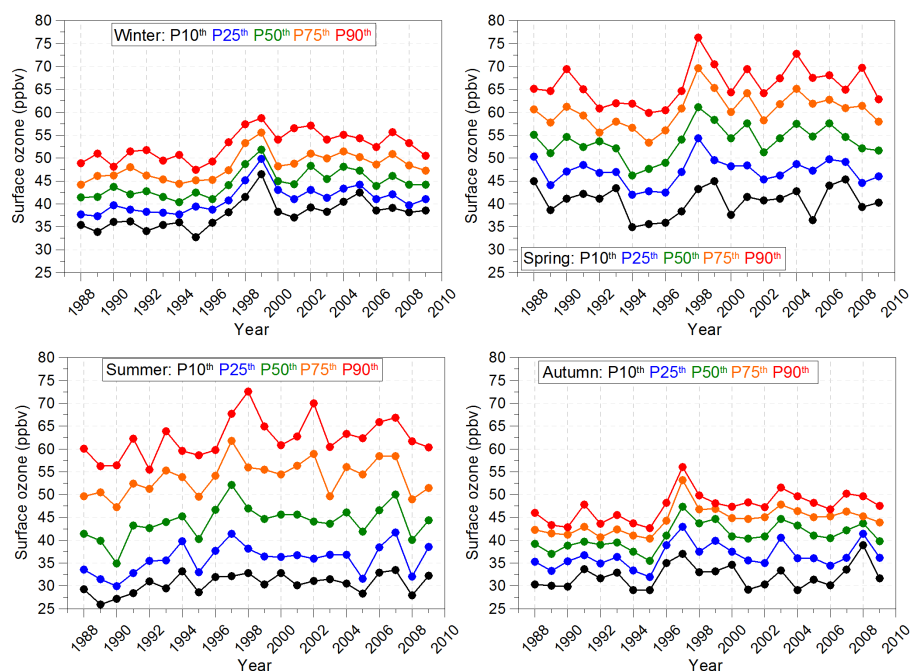

Fig. 3. Long-term (1988–2009) surface O₃ concentrations (night values: 22:00–06:00 UTC) for percentiles 10th, 25th, 50th, 75th and 90th at IZO for winter (JFM), spring (AMJ), summer (JAS) and autumn (OND).

O₃ is observed, with higher altitudes to the north. The highest trajectory altitudes describe an arc-shaped corridor from Western Europe to north-eastern North America. Air masses with low O₃ coming from the Sahara are also recorded associated to very low height trajectories. In spring (April–June) we observe a similar O₃ pattern to winter, but with the following characteristics: (1) the latitudinal gradient is much higher, registering very high values at the northern edge of the cloud trajectories and Western Europe, describing an arc-shaped pathway; (2) contributions from Sahara and southern part of the North Atlantic are lower; and (3) transport from North America is more well defined in this season. The heights of backward trajectories (Fig. 6) show a similar pattern than in winter, although the lowest trajectories from Africa travel at higher altitudes. In summer months (July–September) there is a sharp change because basically only two geographical sectors of air mass pathways are identified: from North America, with associated medium and high O₃ values, and from the Sahara and Northern Sahel, with a lower latitude edge set at 10–15° N, with low and very low O₃ values (Fig. 5). Air masses from North America and North Atlantic travel at relatively high altitude, whereas air masses from Sahara come from low levels (Fig. 6). It is noticeable that in July and August low-level trajectories originate from Western Sahara, while trajectories from the Sahel, and those originated over western North African countries and the Mediterranean Basin travel at mid-high altitudes. In summer time the contribution from Western Europe is at its minimum, and the highest O₃ values describe an arc-shaped path-

way over the North Atlantic similar to that found in spring (Fig. 5). The O₃ and trajectory height patterns of autumn rapidly evolve to resemble those found in winter (Figs. 5 and 6), but with significantly lower O₃ values in the southern part of the trajectories cloud.

3.4 Low surface O₃ concentrations

The frequency distribution of trajectories by geographical sectors for low O₃ values (< P25th) registered at IZO is shown in Fig. 7a. Air masses that most often contribute to low levels of O₃ throughout the year are those from the subtropical North Atlantic (below 30° N). However, in summer, especially in July and August, the Saharan air masses (with 60 % frequency) are the largest contributor to O₃ levels < P25th. There is a secondary maximum of African air masses in March when dust layers occurring at low levels (usually within the MBL) impact IZO on their upper edge, although to a much lesser extent than in summer.

In winter very low O₃ values are recorded also under fog conditions at IZO when the TIL is very high or it simply does not exist (normally with North Atlantic air masses). Hourly O₃ data shows a strong negative correlation with water vapour pressure (not shown here). In summer and autumn low O₃ levels are associated with the arrival of North African air masses that originate from southern Morocco, Western Sahara and Sahelian regions (25–35 % of occurrence frequency of values < P10th). These trajectories show low-level (< 1500 m) “start points”, which are usually associated with

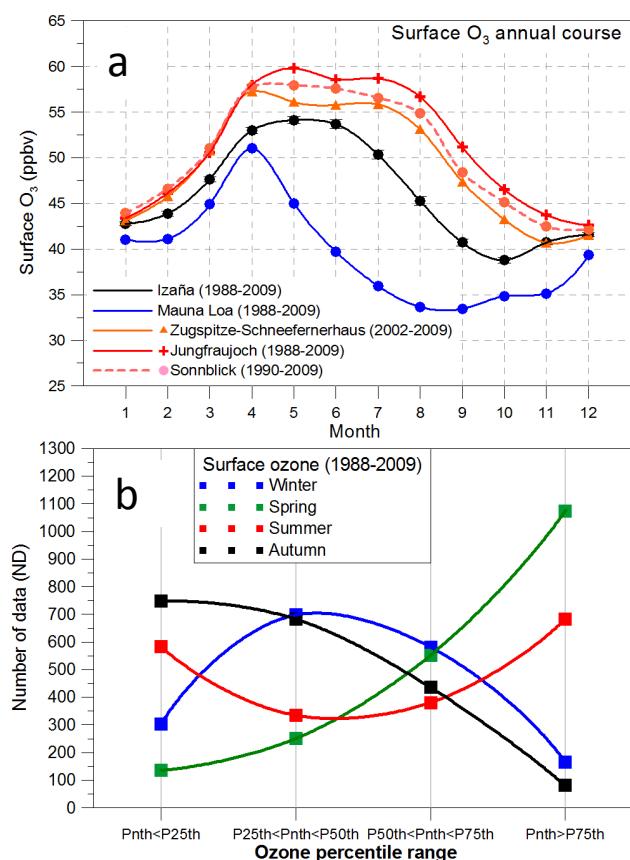

Fig. 4. (a) Annual course of surface O₃ at IZO, Mauna Loa, Zugspitze-Schneefernerhaus, Jungfraujoch, and Sonnblick. Bars associated to monthly mean values at IZO are the standard deviation of the mean. (b) The seasonal distribution of number of surface O₃ daily data (ND) at IZO within the following percentile ranges: $P_{nth} \leq P_{10th}$, $P_{10th} < P_{nth} \leq P_{25th}$, $P_{25th} < P_{nth} \leq P_{50th}$, $P_{50th} < P_{nth} \leq P_{75th}$, $P_{75th} < P_{nth} \leq P_{90th}$ and $P_{nth} > P_{90th}$.

dust storms driven by surface local thermal lows over the Sahara (Prospero and Carlson, 1981).

There is a clear negative logarithmic relationship between PM₁₀ and surface O₃ in all seasons for the period 2002–2009 (Fig. 8a). Surface O₃ daily nocturnal data have been grouped in 10 ppbv bin ranges from the minimum to maximum value. Each point of the plot represents the median value of surface O₃ concentrations associated to the mean value (and corresponding standard deviation of the mean) of PM₁₀ in a determined bin range.

Most of the Saharan air masses have travelled within the African CBL, and a high percentage of them correspond to lower levels (< 1500 m a.s.l.). 67 % of the hourly PM₁₀ records at IZO are lower than $10 \mu\text{g m}^{-3}$, and monthly means of PM₁₀ P75th are below $10 \mu\text{g m}^{-3}$ through the year, except in summer time when significant PM₁₀ concentrations are observed above P80th ($26 \mu\text{g m}^{-3}$).

Bonasoni et al. (2004) found also negative correlation between surface O₃ and coarse dust particles from North Africa at the high altitude Mt. Cimone station (North Italy). Andrey et al. (2010) found decreases of tropospheric O₃ up to 30 % in some layers, between 2 and 6 km altitude, during dust-laden Saharan air mass intrusions over Tenerife, compared to situations of non-Sahara air masses. This result agrees with the relationship between surface O₃ and PM₁₀ found in this work.

The relationship between surface O₃ and ²¹⁰Pb is shown in Fig. 8b. In summer we obtain a logarithmic fit with a good correlation which resembles the O₃–PM₁₀ fit in the same season. Prospero et al. (1995) had reported preliminary results of O₃–²¹⁰Pb relationship for summer time. However, in spring (mainly in April) and autumn (mainly in December), when Saharan low-level intrusions over the Canary Islands occur (Alonso-Pérez et al., 2007), IZO is only slightly impacted by the top of the Saharan Air Layer (SAL). So we can see Saharan CBL signature with relatively high values of ²¹⁰Pb, although the O₃–²¹⁰Pb relationship is not as clear as that seen in summer. In winter no correlation between surface O₃ and ²¹⁰Pb is found.

The low O₃ values associated with African trajectories which, in turn, cause a systematic rise in relative humidity records at IZO (Cuevas, 1995), might be due to a sum of all or some of the following causes: (1) air masses come from lower levels within the Saharan CBL where O₃ concentrations are generally low (Güsten et al., 1996); (2) air masses originate from similar or lower latitudes which are not enriched with the latitudinal O₃ gradient existing in spring and summer in the Northern Hemisphere (London and Liu, 1992); (3) O₃ might be destroyed by dry deposition on suspended dust particles because of a larger surface area to dry deposition (Güsten et al., 1996); and (4) heterogeneous removal processes on dust aerosol by nitric acid (de Reus et al., 2000).

3.5 High surface O₃ concentrations

Figure 7b shows the monthly frequency of air masses that contribute most to O₃ values > P75th. Air masses from North America and oceanic sectors that have travelled over the North Atlantic are the largest contributors by far to high concentrations of O₃ at IZO. The highest daily O₃ values (> P90th) are observed in May and June, and in the first half of summer time (July and early August). Air mass residence times associated to O₃ concentrations between P75th and P90th (not shown here) show maximum values over the eastern United States (US) and North Atlantic between 30° and 55° N in winter, over the North Atlantic, from 25° to 55° N in spring, and near the Canary Islands and over north-western Africa in summer. In autumn the maximum residence times are much shorter and located to the northernmost position.

Summer time is very interesting since O₃ records differ markedly from other seasons because the O₃ concentration

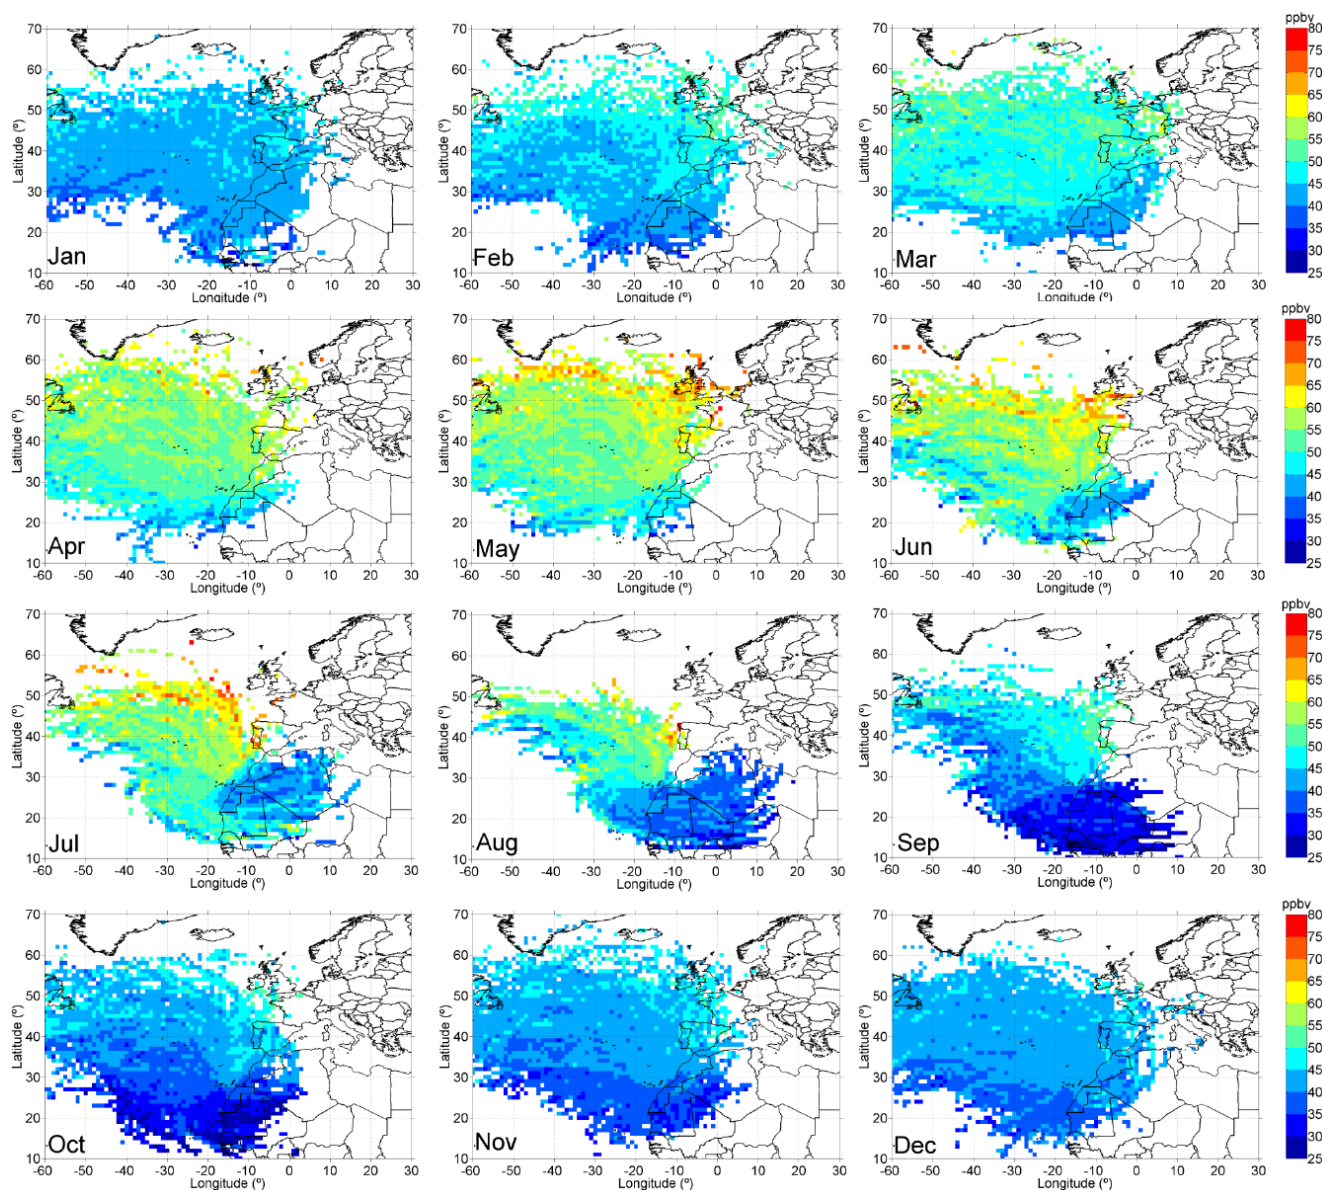

Fig. 5. Surface O₃ MCAR plots for each month of the year for the period 1988–2009. Colour bars indicate O₃ concentration in ppbv.

undergoes large and rapid changes (Cuevas, 1995; Rodríguez et al., 2004), often from day-to-day. The alternation of dust transport from the Saharan CBL – lasting 3–7 days – with the arrival of air masses from high levels over the North Atlantic, modulated by the Azores anticyclone, accounts for these sudden changes in O₃ concentration.

3.6 Upper troposphere contribution

We have computed PV_{\max} found by daily 5-day backward trajectories when intercepting ECMWF PV-reanalysis fields for each day of the period 1988–2009. We have observed that mean values of PV_{\max} in all seasons are slightly higher than 0.6 PVU. The average PV ranges approximately from

0.3 to 0.5 PVU in the low and middle troposphere (e.g. Rao et al., 2003), while 1 PVU is a typical value of the upper troposphere. Therefore, it is noteworthy that in 10 % of days in winter and autumn, backward trajectories have been impacted by upper-troposphere air masses with $PV > 1$ PVU. Some of them might even have been affected by stratospheric intrusions mixed with upper-troposphere air masses.

Seasonal averages of PV_{\max} values have been plotted for several surface O₃ bins (Fig. 9a) for winter, spring, summer and autumn. A fair O₃– PV_{\max} correlation is found in all seasons with an O₃– PV_{\max} slope $\sim 100 \text{ ppbv PVU}^{-1}$ for winter, spring and summer, and a slope slightly lower $\sim 53 \text{ ppbv PVU}^{-1}$ for autumn. These results emphasize the

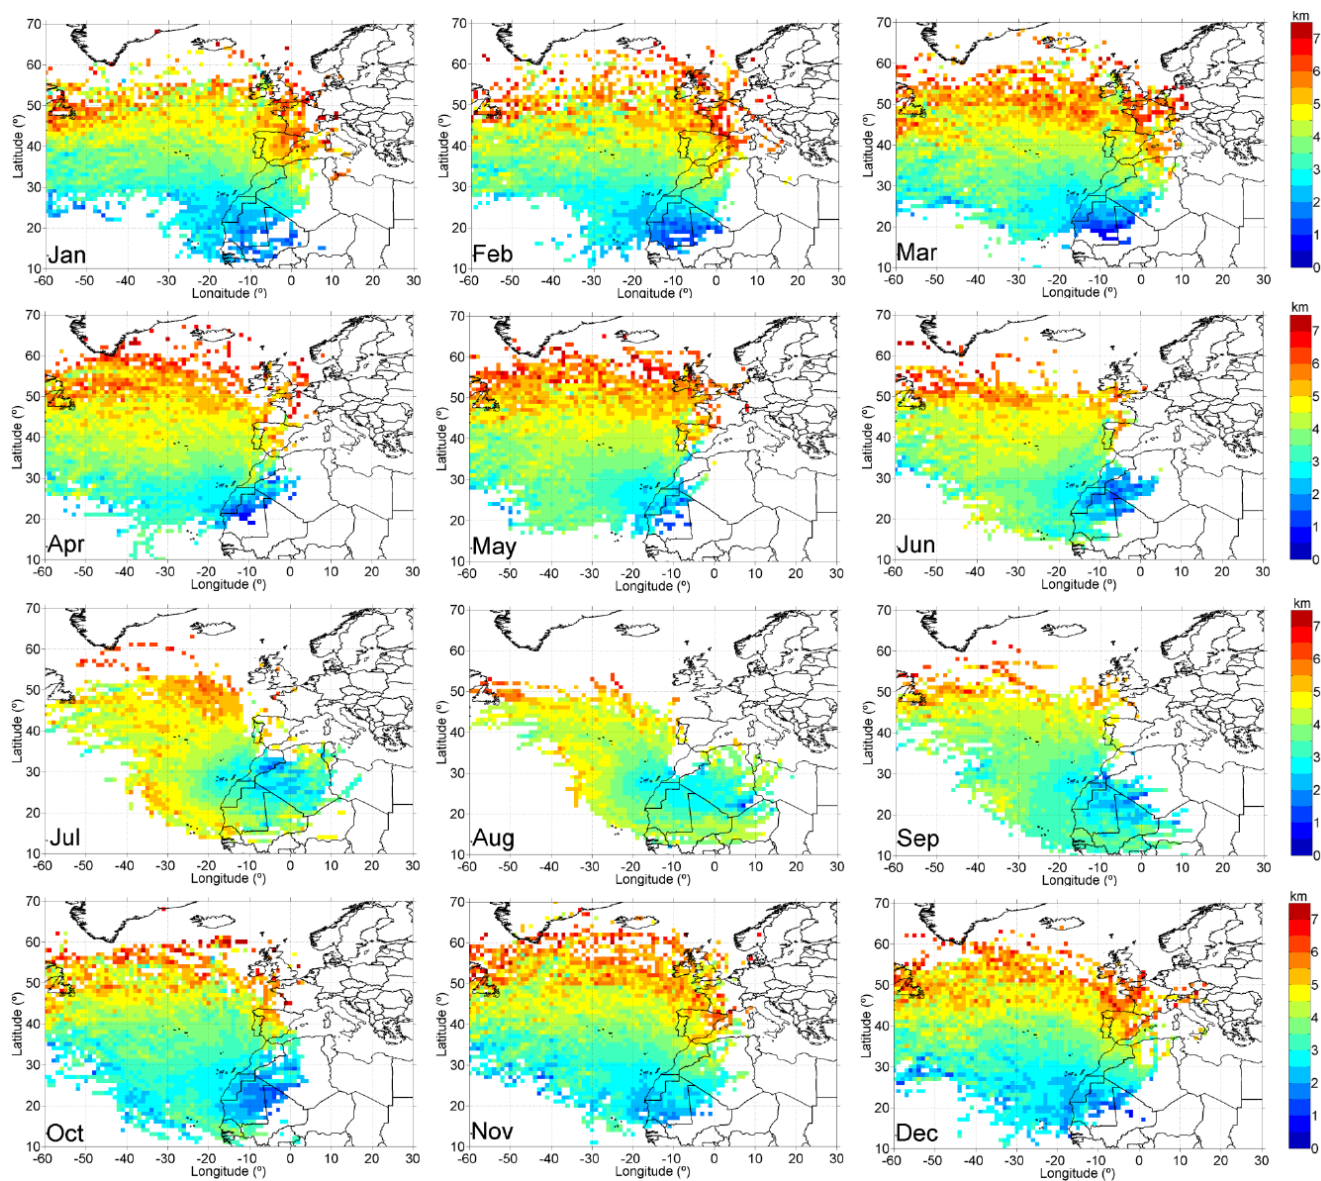

Fig. 6. Backward trajectory mean height plots for each month of the year for the period 1988–2009. Colour bars indicate height in kilometers.

importance of air mass subsidence regardless of the origin of O₃ measured at IZO. Cooper et al. (2002) found over the western North Atlantic an O₃/PV ratio of ~ 72 ppbv PVU⁻¹ in spring time and ~ 42 ppbv PVU⁻¹ in late summer/early autumn. O₃/PV ratios found by Rao et al. (2003) at 500 hPa in Northern Europe range from 60 to 120 ppbv PVU⁻¹, which are of the same order as the O₃/PV_{max} ratios found at IZO.

Figure 10 shows the spatial distribution of averaged PV_{max} recorded by daily 5-day backward trajectories when they are crossed with the ECMWF PV-reanalysis fields for each season. Thresholds of 1 and 1.6 PVU are marked with black lines. PV_{max} maps provide an estimation of geographical regions of potential STT transport. PV_{max} might work

as a meridional height coordinate: the highest and more northerly the air mass travels, the more PV_{max} is associated. In Fig. 10 a latitudinal distribution, with much higher values of PV_{max} in the north, is clearly appreciated. In mid-latitudes there is a belt with relatively high values between 45° N and 55° N that crosses the North Atlantic. This is consistent with the distribution of backward trajectory heights pattern (Fig. 6). In winter and spring this high PV_{max} belt coincides with the corridor where anthropogenic pollution is exported from North America to the North Atlantic (Cooper et al., 2002; Hegarty et al., 2009), as will be discussed later on. In summer PV_{max} values are substantially reduced. However, it is noticeable the relatively high PV_{max} values found in the vicinity of the Canary Islands over North Africa. This result

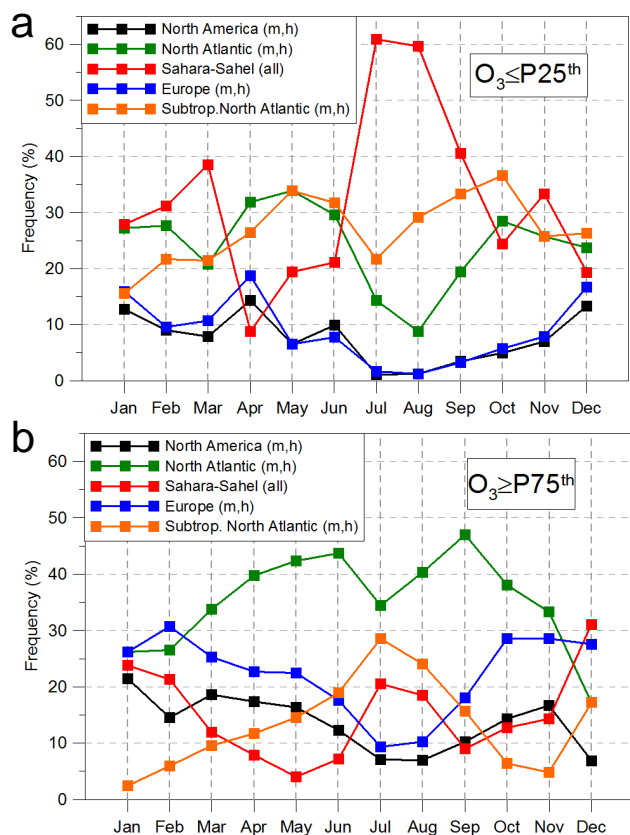

Fig. 7. (a) Monthly mean percentage of air mass types arriving to IZO for $O_3 < P25^{th}$ for the period 1988–2009. (b) Monthly mean percentage of air mass types arriving to IZO for $O_3 > P75^{th}$ for the period 1988–2009 (bottom panel).

is also consistent with the high altitudes of backward trajectories observed over North Africa and the Mediterranean Basin in July and August (Fig. 6).

The relationships between surface O_3 and 7Be are shown in Fig. 9b for winter, spring, summer and autumn. The slope of O_3 – 7Be best fit corresponding to winter is similar to the slope of O_3 – 7Be best fit found by Dibb et al. (unpublished manuscript, 2006; www.espo.nasa.gov/docs/intex-na/Dibb_et.al.INTEXA.pdf) in mid and upper troposphere over North America during INTEX A flight experiment ($1 \text{ mBq m}^{-3} = 0.037 \times \text{fCi m}^{-3}$).

Li et al. (2002b) simulated 7Be and ^{210}Pb concentrations at Tenerife for summer time and suggested that the positive O_3 – 7Be and negative O_3 – ^{210}Pb correlation simply reflects the respective common vertical trends. However, Cuevas (1995) and Cuevas et al. (2000) reported some case analysis of high- O_3 and high- 7Be data associated with air mass transport from the western part of cut-off lows (COLs) developed to the west of the Iberian Peninsula in spring and summer. Rodríguez et al. (2004) have also shown that episodes of $O_3 > P90^{th}$ at IZO are associated with strong subsidence in the FT at the western side of COLs located between the Canary Islands

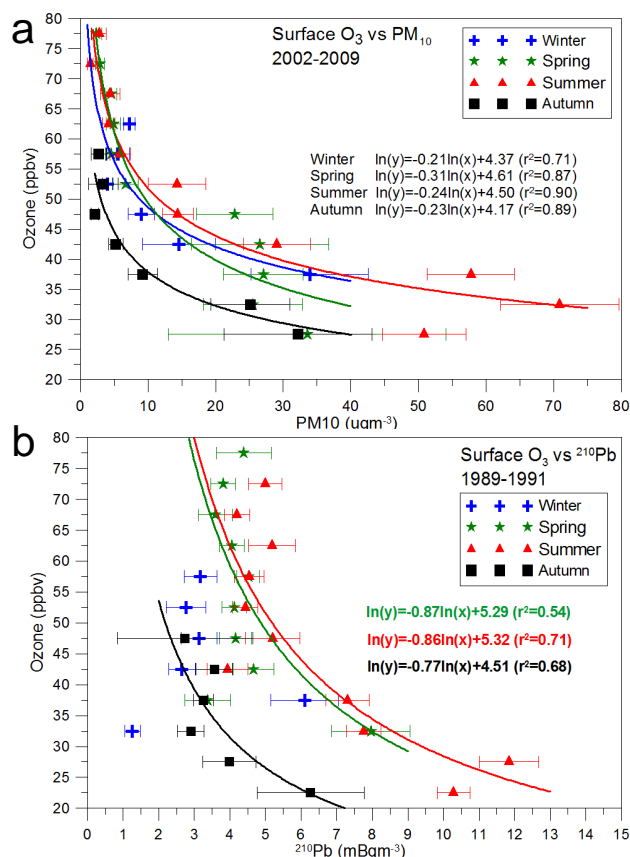

Fig. 8. (a) PM_{10} (μm^{-3}) vs. surface O_3 (ppbv) at IZO for winter (JFM), spring (AMJ), summer (JAS) and autumn (OND) in the period 2002–2009. (b) ^{210}Pb (mBq m^{-3}) vs. surface O_3 (ppbv) for the same seasons in the period 1988–1991. Surface O_3 daily nocturnal data have been grouped in 10 ppbv bin ranges from the minimum to maximum value. Each point of the plot represents the median value of surface O_3 concentrations associated to the mean values of PM_{10} or ^{210}Pb in a determined bin range. The standard deviation of the mean (SDOM) associated to PM_{10} and ^{210}Pb mean values is represented by horizontal bars.

and the Iberian Peninsula. The STT processes are frequently associated to COL developments in the subtropical North Atlantic (Kentarchos et al., 2000). Cuevas and Rodríguez (2002), with an 11-yr climatology of ECMWF isentropic potential vorticity fields, concluded that the frequency of COLs and deep lows over the North Atlantic reach a maximum in May–July, in areas surrounding the Iberian Peninsula where these lows are more frequent. James et al. (2003), with a 15-yr climatology of STT exchange found similar results, concluding that the corridor parallel to the Atlantic coast of the Iberian Peninsula over the ocean down to the Canaries frequently receives stratospheric air.

Reiter et al. (1983) suggested a 7Be threshold value of 8 mBq m^{-3} , above which an air mass probably has stratospheric signature. This value has been used by several

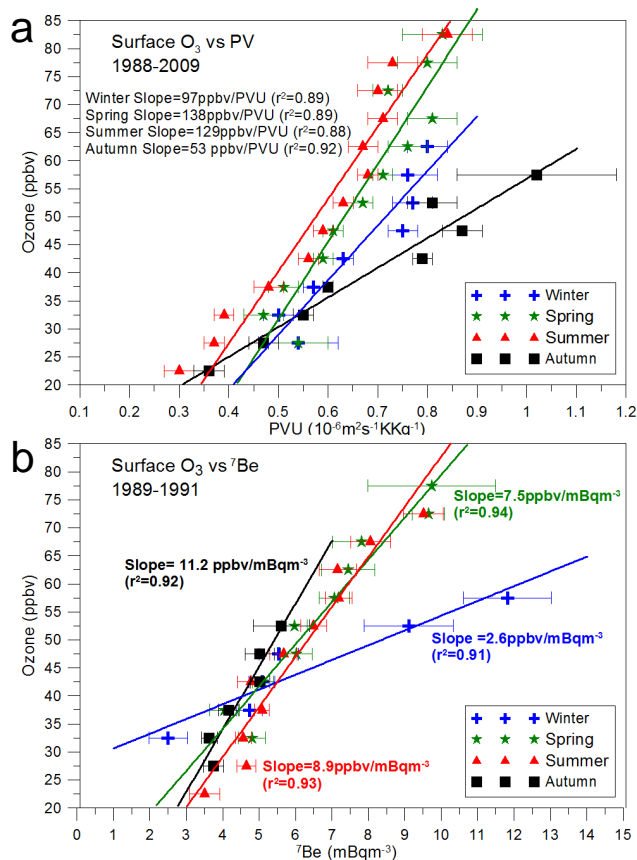

Fig. 9. (a) PV_{\max} ($1 \text{ PVU} = 10^{-6} \text{ m}^2 \text{ s}^{-1} \text{ K Kg}^{-1}$) vs. surface O₃ (ppbv) at IZO for winter (JFM), spring (AMJ), summer (JAS) and autumn (OND) in the period 1988–2009. (b) ^7Be (mBq m^{-3}) vs. O₃ ozone (ppbv) at IZO for the same seasons in the period 1989–1991. Data have been grouped and depicted as for Fig. 8.

authors to identify stratospheric intrusions in high mountain stations (Zanis et al., 1999; Stohl et al., 2000; Bonasoni et al., 2000; Cristofanelli et al., 2006), although it is not possible to consider ^7Be as an unambiguous stratospheric tracer (Zanis et al., 1999; Stohl et al., 2000). Gerasopoulos et al. (2001) found at four high-altitude alpine stations that high- ^7Be values (above 6 mBq m^{-3}) correspond to air masses from the north and high altitudes, as it is characteristic for stratospheric intrusions. Reiter et al. (1983) showed that the range of ^7Be values $> 7.4 \text{ mBq m}^{-3}$ corresponds to direct stratospheric intrusions near the station, without a long advection path. The third quartile of ^7Be data series at IZO is 8.2 mBq m^{-3} , and stratospheric air mass intrusions normally reach the ground after considerable mixing with tropospheric air. Therefore, a threshold value of 8 mBq m^{-3} is reasonable to estimate the impact of UTLS air masses at IZO.

We have estimated the impact on O₃ at IZO of air masses with daily mean values of $^7\text{Be} > 8 \text{ mBq m}^{-3}$. Results are summarized in Table 3. The percentage of cases per season

Table 3. Basic statistics of surface O₃ at IZO for days with daily $^7\text{Be} > 8 \text{ mBq m}^{-3}$. The term “climat.” refers to the O₃ mean when considering all the ozone values within the indicated period independently of the ^7Be value.

O ₃ (ppbv)	Winter	Spring	Summer	Autumn
%cases	3.8	14.6	8.9	1.4
Mean	47.8 ± 1.9	60.3 ± 1.4	56.8 ± 2.2	46.3 ± 4.1
Median	45.0	59.4	56.8	42.3
Climat.	44.7 ± 0.3	53.6 ± 0.4	45.5 ± 0.5	40.4 ± 0.3

with $^7\text{Be} > 8 \text{ mBq m}^{-3}$ is significant in spring and summer (14.6 % and 8.9 % of cases/season, respectively), while in winter and autumn the percentage of cases/season is much lower (3.8 % and 1.4 %, respectively). The impact of high ^7Be events on O₃ values at IZO is considerable, recording in these events O₃ averages that are 7 ppbv and 11 ppbv above O₃ climatological values (considering all days independently of ^7Be values) for spring and summer, respectively.

We have plotted the residence time of air masses with daily $^7\text{Be} > 8 \text{ mBq m}^{-3}$ for each season of the year in Fig. 11. Higher residence times are observed in mid-latitudes over the north-eastern US extending over the North Atlantic in winter. In spring several maximum residence times are observed over the North Atlantic, but a maximum which extends along a north–south corridor over the eastern North Atlantic stretching from Great Britain to the Canary Islands is notable. Similar results were obtained by Rodríguez et al. (2004) for O₃ values within P50th–P100th in spring. In summer the corridor is strengthened to the vicinity of the Canary Islands, and a secondary maximum is found in north-eastern North America extending over North Atlantic. In autumn this maximum is also identified, and some secondary high residence times near the Canary Islands are observed. In relation to the height at which air masses were travelling, it is noteworthy that in the spring and summer they come from altitudes above 5 km. To summarize, the source regions of high ^7Be air masses with maximum impact on O₃ at IZO are registered in a region around the Canaries extending to the north over North Atlantic in spring and summer. This region coincides with areas where COL developments and STT processes have been reported in previous studies (e.g. Cuevas and Rodríguez, 2002; James et al., 2003; Rodríguez et al., 2004). Nieto et al. (2005), from a 41-yr climatology of COLs in the Northern Hemisphere, reported three preferred areas of COLs occurrence, one of them being the southern European and the eastern Atlantic coast, in agreement with our results.

Recently, Hegarty et al. (2009) revealed that O₃ observations from TES (Tropospheric Emission Spectrometer) also evidence stratospheric intrusions associated with the cyclones over the North Atlantic. According to Wernli and Bourqui (2002), “deep exchange” denotes events where air parcels are rapidly transported from the stratosphere down to levels below 700 hPa level (deep STT). The STT climatology

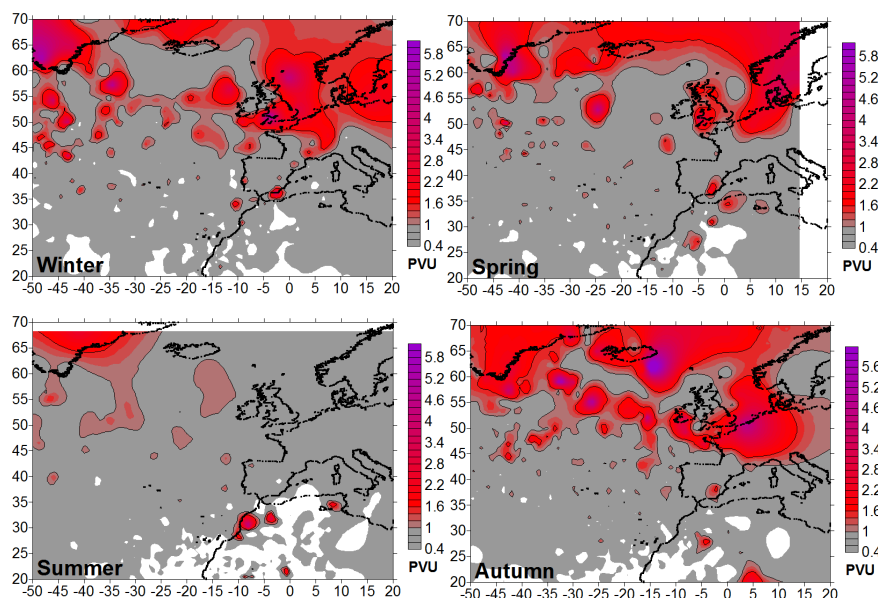

Fig. 10. PV_{max} maps for winter (JFM), spring (AMJ), summer (JAS) and autumn (OND) in the period 1988–2009. They have been constructed from the coordinates of PV_{max} values found by 5-day backward trajectories arriving at IZO every day at 00:00 UTC in ECMWF PV-reanalysis fields. Thresholds of 1 and 1.6 PVU are marked with black lines.

from Sprenger and Wernli (2003) shows that deep STT is particularly strong in the 40–65° N latitude band over the North Atlantic storm track region in winter, just in the high PV_{max} passageway we have found in this season (Fig. 10).

3.7 Relationship between O₃ and CO

Hegarty et al. (2009) reported that composites of O₃ and CO retrievals from TES showed the main pollution export from North America extended in a band from 30° N to 45° N. Strong positive correlations between CO and surface O₃ are found in maritime stations off the coast of Canada (Kasibhatla et al., 1996). These positive correlations are attributed to the transport of photochemically generated O₃ from North America out over the North Atlantic (Parrish et al., 1993).

The concentration of CO at IZO shows a general increase during autumn and winter until the maximum is reached in late March, while the minimum is observed in middle August (Gómez-Peláez et al., 2012). The relationships between surface O₃ and CO at IZO for each season of the year are shown in Fig. 12. The good correlation between O₃ and CO at IZO in winter (with an O₃/CO slope of 0.84 ppbv ppbv⁻¹), in spring when surface O₃ is within 30–50 ppbv and CO within 85–115 ppbv (with an O₃/CO slope of 0.91 ppbv ppbv⁻¹), and in autumn with an O₃/CO slope of 0.81 ppbv ppbv⁻¹ for surface O₃ values below 35 ppbv, supports the hypothesis of long-range transport of photochemically generated O₃ to IZO in these seasons, likely from North America according to the paths of the trajectories (Fig. 5). However, the lack

of correlation between surface O₃ and CO found in summer suggests that significant O₃ enhancements are not directly caused by long-range transport of anthropogenic pollution in this season. These results agree with Li et al. (2002b) who found the strongest export of anthropogenic CO from North America in winter, and the weakest in summer.

Chin et al. (1994) found an O₃/CO slope ~ 0.3 ppbv ppbv⁻¹ in aged air masses at rural sites in eastern North America. Hegarty et al. (2009) found that, under some meteorological conditions, some cyclones near the east coast of the US produced the greatest export to the lower FT with O₃ > 65 ppbv and a well-defined O₃–CO correlation with an O₃/CO slope ~ 0.20 ppbv ppbv⁻¹, indicative of the overall impact of photochemical processes in North American continental export. However, Honrath et al. (2004) reported for the high mountain station of Pico in Azores, in the middle of the North Atlantic, that O₃ and CO were correlated during North American outflow events, with a slope averaging 1.0 ppbv ppbv⁻¹ – more than 80 % larger than O₃/CO ratios observed in the eastern US and near-shore outflow region. Honrath et al. (2004) explained these high ratios by the fact that air masses from North American outflow events have undergone days of photochemical processing, increasing the O₃/CO ratio.

A 3-yr “climatology” of daily O₃/CO ratios is shown in Table 4. Mean (\pm standard deviation), median, P25th and P75th of O₃/CO ratios have been calculated for each season. The highest concentrations of CO at IZO (> 133 ppbv, above the P90th) are observed in winter and spring, mostly coming

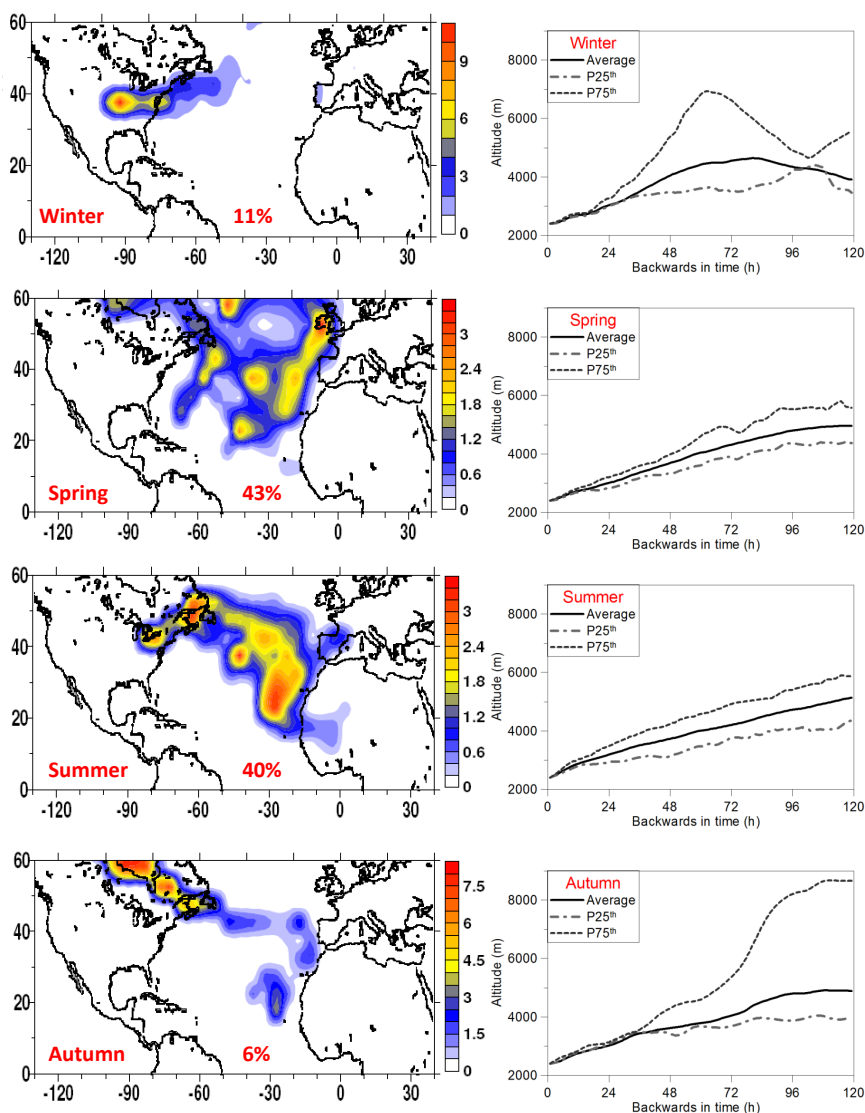

Fig. 11. Residence times and transport pathways of air masses with daily ${}^7\text{Be} > 8 \text{ mBq m}^{-3}$ and corresponding averaged backward trajectories heights for each season of the year. Colour bars indicate the residence time in arbitrary units. In backward trajectory heights the mean values P25th and P75th are plotted.

from North America (not shown here). In order to determine the impact of long-range transport of American pollution, and the origin of the fairly good O₃–CO correlation, we have analyzed the events in which, at least during five consecutive days, a good correlation ($r > 0.75$) between hourly concentrations of O₃ and CO is observed within the period 2008–2011. We have separated the events in five groups according to O₃ ranges and seasons. The O₃/CO ratios are summarized in Table 5. In winter the events Type 1 and Type 2 show O₃/CO ratios of 0.41 and 0.43 ppbv ppbv^{−1}, respectively, which lie within the climatological median–P100th O₃/CO range for this season (Table 4). The events with the highest O₃/CO values ($0.53 \pm 0.07 \text{ ppbv ppbv}^{-1}$) were recorded in spring, all of them for O₃ > P75th (Type 3) being within

the climatological P25th–P75th O₃/CO range for O₃ > P75th (Table 4). In summer the only 7-day event recorded (Type 4) showed a mean O₃/CO ratio of $0.67 \text{ ppbv ppbv}^{-1}$, which is lower than the climatological mean for O₃ > P75th (Table 4). In autumn events of high O₃–CO correlation, associated to long-range transport, were also recorded (Type 5), but the averaged O₃/CO ratio ($0.45 \pm 0.04 \text{ ppbv ppbv}^{-1}$) is lower than the climatological mean for this season.

As demonstrated in Table 5, most of the events showing a good correlation between O₃ and CO, and thus unambiguous transport of likely anthropogenic O₃, are observed in spring and winter. Thus, a residence time analysis of air masses with an O₃–CO correlation > 0.75 has been performed for these two seasons (Fig. 13a). The results

Fig. 12. CO (ppbv) vs. surface O₃ (ppbv) at IZO for winter (JFM), spring (AMJ), summer (JAS) and autumn (OND) in the period of 2008–2011. Data have been grouped and depicted as for Fig. 8.

Table 4. Averaged O₃/CO ratios (ppbv ppbv^{−1}) at IZO for winter, spring, summer and autumn (all cases and those with O₃ > P75th), and estimated type of air mass (FP = Fresh Pollution; A = Aged air mass; UT = Upper Troposphere). Types of air masses have been labelled according to the O₃/CO range values.

	Mean ± SD	Median	P25th	P75th	Type
Winter	0.39 ± 0.07	0.38	0.34	0.44	FP
O ₃ > P75th	0.42 ± 0.06	0.40	0.37	0.45	FP
Spring	0.47 ± 0.10	0.46	0.40	0.53	A
O ₃ > P75th	0.58 ± 0.10	0.56	0.51	0.62	A + UT
Summer	0.56 ± 0.15	0.55	0.44	0.65	A + UT
O ₃ > P75th	0.71 ± 0.13	0.70	0.61	0.78	A + UT
Autumn	0.47 ± 0.10	0.47	0.41	0.54	A
O ₃ > P75th	0.54 ± 0.08	0.54	0.49	0.60	A + UT

identify a main contribution from pollution episodes over North America in winter, with backward trajectory heights below 4 km, whereas in spring aged air masses (previously transported from North America) are found over North Atlantic at slightly higher altitudes (above 4–5 km), although it must be stated that there is substantial overlap in the ranges of altitude of both seasons (Fig. 13a and b). In both cases maximum residence times are observed over the eastern US and western North Atlantic, on a corridor bounded by the parallels 20° and 50° N. High trajectories suggest that pollution was injected previously over the US east coast into the FT. These results agree with previous studies in which the warm conveyor belt associated with cyclonic pressure systems lifts O₃ produced photochemically in the CBL up into the FT over eastern continental US, and then the O₃ is transported by the westerlies across the North Atlantic onto Europe (Berkowitz et al., 1996; Stohl and Trickl, 1999; Cooper and Parrish, 2004).

Table 5. O₃/CO ratios at IZO for events with hourly O₃–CO data correlation $r > 0.75$.

	O ₃ range (ppbv)	O ₃ /CO (ppbv ppbv ^{−1})	Cases (2008–2011)
Type 1	P50th–P75th	0.41 ± 0.03	8 in winter
Type 2	P75th–P100th	0.43 ± 0.07	5 in winter
Type 3	P75th–P100th	0.53 ± 0.07	58 in spring
Type 4	P75th–P100th	0.67 ± 0.14	7 in summer
Type 5	P75th–P100th	0.45 ± 0.04	7 in autumn

In winter the O₃/CO ratios found during long-range transport events (~ 0.42 ppbv ppbv^{−1}) agree quite well with the climatological ratio for this season. The ratios do not differ substantially from those calculated for high O₃ values (> P75th) and from those obtained for all values of O₃ for the study period. So, in winter, when the westerlies blow with their maximum intensity, O₃ measured at IZO might have a large contribution of long-range pollution transport from North America. The O₃/CO ratios reported near the pollution sources range from 0.2 to 0.3 ppbv ppbv^{−1} (e.g. Chin et al., 1994; Dickerson et al., 1995; Li et al., 2002b; Hegarty et al., 2009). The higher ratios found at IZO imply an additional O₃ amount and/or CO reduction which may arise, in part, from photochemical processing during transporting. In these conditions we could consider that the transport events labelled Type 1 and Type 2 (Table 5) correspond to fresh pollution that is transported rapidly from North America to the subtropical FT. In spring the climatological O₃/CO ratios differ notably if we consider O₃ values > P75th (~ 0.58 ppbv ppbv^{−1}) or all O₃ values (~ 0.47 ppbv ppbv^{−1}). The average ratio found in pollution transport events labelled Type 3 (~ 0.53 ppbv ppbv^{−1}) is between these two values. This may be due to the fact that in spring a higher insolation speeds up in situ photochemistry in the FT (Yienger et al., 1999), and also to large-scale downward transport of O₃-rich air from the upper troposphere. Thus, O₃/CO ratios between 0.47 and 0.54 ppbv ppbv^{−1} might be typical of aged air masses originating in North America, while ratios above 0.54 ppbv ppbv^{−1} might be explained by a mix of aged air masses and upper troposphere O₃-rich air masses. These assumptions are consistent with the analysis of residence times and heights of air masses characterized by high O₃–CO correlation (Fig. 13a). In spring air masses come normally from higher altitudes than in winter, and the maximum of air masses residence times is located north-east of the maximum found in winter, over western and central North Atlantic, further from pollution sources. On the other hand the seasonal averaged O₃/CO slopes (0.84 ppbv ppbv^{−1} for winter and 0.91 ppbv ppbv^{−1} for spring; see Fig. 12), which include all kinds of O₃ production and transport processes are higher than the O₃/CO ratios found in well-identified, long-range pollution transport (0.42–0.53 ppbv ppbv^{−1}), suggesting the contribution of a second source of O₃. The corridor of North

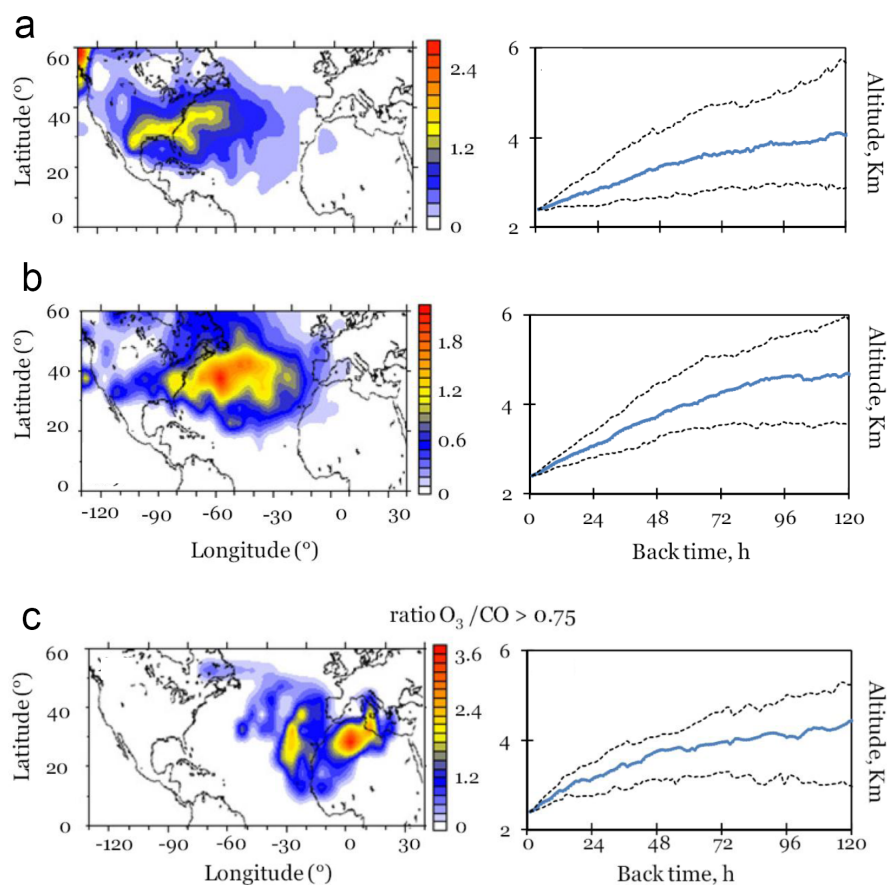

Fig. 13. Residence time of air masses (corrected by central convergence) that show an O₃–CO hourly correlation $r > 0.75$ for winter and spring (a, b). Colour bars indicate residence time in arbitrary units. Mean, P25th and P75th of 5-day backward air masses travelling altitude for these events in winter and spring are depicted. (c) Residence time of air masses that show an O₃/CO hourly ratio > 0.75 ppbv ppbv^{−1}, and corresponding averaged backward trajectories height.

American pollution events (Cooper et al., 2002; Hegarty et al., 2009) overlaps to a large extent the belt with relatively high PV_{max} values found in winter and spring between 45° and 55° N, crossing the North Atlantic (Fig. 10). Differences found between the O₃/CO ratios at IZO and seasonal O₃/CO slopes, on the one hand, and between the latter with O₃/CO ratios near the pollution sources, on the other hand, could be explained with the following conceptual model based on two processes: (1) O₃ continued to be produced in the plume during transportation in the FT (Honrath et al., 2004; Mao et al., 2006); and (2) contribution from the upper-level air transported downward in the descending dry airstream of cyclones over the North Atlantic, which may have enhanced the lower tropospheric O₃ keeping levels high (Hegarty et al., 2009). Bearing in mind that high O₃ values at IZO are normally associated to high-altitude backward trajectories – high-PV and high-⁷Be values – this conceptual model might conciliate the apparently contradictory results of finding simultaneous positive O₃–CO correlation (Fig. 12), on the one hand, and positive O₃–PV (Fig. 9a) and O₃–⁷Be (Fig. 9b) corre-

lations, on the other hand, in winter and spring. Therefore, a mixture of photochemical O₃ produced as a result of pollution export from North America and O₃ from stratospheric intrusions over the North Atlantic into the FT seems to be a likely process. This result agrees with Hegarty et al. (2009) who highlighted that some frequent meteorological patterns could produce a well-stirred region of the atmosphere over the North Atlantic that continuously interleaves air masses originating from the lower mid- and upper troposphere, and thus favouring the mixing of polluted air masses with stratospheric O₃-rich air masses.

Concerning high O₃ values recorded at IZO in summer time some authors (e.g. Schmitt and Carretero, 1992; Raes et al., 1997; Li et al., 2002b) hypothesized that, under some conditions during the summer, pollutants and photochemically-produced O₃ can be transported to the Canary Islands from the Iberian Peninsula and adjacent regions in Europe. Such conditions would be favoured by a coupled system consisting of the Iberian thermal low at ground level and anticyclonic subsidence aloft (Millán et al., 1997).

However, this transport is most likely to occur within the MBL and not in the FT, as stated by Stohl et al. (2002) who analyzed the southward flow of European pollution in summer over the Mediterranean Basin and North Africa. The MCAR plots of O₃ pathways (Fig. 5) do not show significant transport of O₃ from Europe, and there is no relationship between O₃ and CO (Fig. 12). These results suggest a low probability of occurrence of pollution transport from Europe within the subtropical FT over the North Atlantic. These results agree with Duncan and Bey (2004) who concluded that there was no evidence of a summer time CO maximum at IZO in either the observations or the model simulations they performed for IZO. Concerning potential pollution from North America, we have found a single 7-day long-range transport pollution event at Izana in this season. Owen et al. (2006) documented that, on average, 38 % of the North American CO export occurs below 3 km altitude, and that advection of pollution layers at low levels, but decoupled from the BML, is responsible for the majority of transport to the central North Atlantic during summer time. However, in summer air masses arriving to IZO from the North Atlantic show a strong subsidence (see Fig. 6), most of them travelling at levels higher than 3 km. Moreover, aged air masses from North America that recirculate, turning around the Azores high anticyclonically (Auvray and Bey, 2005), are decoupled from the air mass pathways to IZO for the same reason. This may be the explanation for finding lower O₃/CO ratios at IZO than at the Azores Pico station.

The climatological O₃/CO ratios at IZO in summer time are significantly higher: 0.56 ppbv ppbv⁻¹ if we consider the whole dataset, and 0.71 ppbv ppbv⁻¹ for O₃ > P75th (P75th O₃/CO ratio ~ 0.78 ppbv ppbv⁻¹). We have analyzed all the episodes in which O₃/CO ratio > 0.75 ppbv ppbv⁻¹. In these cases O₃ does not correlate with CO (O₃–CO correlation < 0.1). We have identified 41 cases in the period 2008–2011, 10 % of them in spring and 90 % in summer. The median value of the relative humidity associated to these events was 12 %, so very dry air suggesting a mid–upper troposphere origin. The residence time analysis shows two predominant origins of the air masses arriving at IZO (Fig. 13b): one located over North Africa and the central Mediterranean Basin, and the other one in a corridor stretching from the Canary Islands to the west of the Iberian Peninsula. These air masses come from altitudes higher than 4 km, showing a strong subsidence. All these events are associated with COL or deep low developments, which indicates they come from the upper troposphere and likely could be influenced by STT processes. The geographical origin of these events agrees with the PV_{max} distribution over North Africa (Fig. 10), and the maximum residence time distribution of air masses with ⁷Be > 8 mBq m⁻³ (Fig. 11). These results also agree with Nieto et al. (2005) who identified North Africa and the Mediterranean Basin (centred over the Italian Peninsula), and the corridor between the Canary Islands and the west of the Iberian

Peninsula as main areas of occurrence of COLs in summer time in the Northern Hemisphere.

3.8 The role of the NAO in tropospheric O₃ budget over the subtropical North Atlantic

The large swing in the phase of the NAO between 1995 and 1996 brought international attention to the physical connection between the NAO and e.g. availability of water in Scandinavia for hydropower generation (Hurrell et al., 2003). Indeed, changes in time series pattern have also been observed in surface O₃ records at IZO between 1996 and 1998 (Fig. 3). Logan et al. (2012) show a significant change in monthly mean time series of surface ozone at the alpine stations in 1997. These changes cannot be attributed to changes in O₃ precursors, but to dynamical processes.

Positive phases of NAO indicate stronger Azores high and stronger Icelandic low and thus more active westerlies over the North Atlantic above 50° N. However, in lower mid-latitudes and in the subtropical North Atlantic, winter positive phases of NAO mean less zonal west-to-east transport. Positive NAO also implies drier conditions than average over northern Africa and a strong subtropical high pressure over the North Atlantic resulting in an increase of dust mobilization through strengthening of trade winds over the Sahara (Chiapello et al., 2005; Evan et al., 2006), and higher frequency of dust intrusions over the subtropical North Atlantic, and specifically over the Canaries (Alonso-Pérez et al., 2011). As we have shown in previous sections, Saharan air masses loaded with mineral dust are associated with low concentrations of surface O₃ at IZO. The negative phase of NAO results in a higher flow of westerlies in the range 30°–45° N, as can be derived from the circulation patterns over the North Atlantic under positive and negative phases of the NAO shown by Hurrell and Dickson (2004).

Figure 14 shows the correlation between NAO and the zonal component of the wind (*u*) at 700 hPa (NCEP reanalysis) in winter, spring, summer and autumn for the entire period 1988–2009. A strong negative correlation is found in winter and autumn within the 20–40° N belt, with a weaker correlation in spring. These results indicate a more effective air mass transport from North America to the Canaries within the low mid- and subtropical latitude belts (between 20° and 40° N) with negative phase of NAO. Hence, this “transport belt” appears to be more active over the subtropical North Atlantic during negative phases of NAO in winter and spring. The effect of intercontinental transport is expected to be weaker in summer (Li et al., 2002a).

Hurrell et al. (2003) concluded that, generally, positive NAO phase winters are associated with a north-eastward shift in the Atlantic storm activity. These results agree with the findings of Andrade et al. (2008), who reported that the inter-annual correlation between the enlarged winter (October to March) NAO index and the total number of storms observed in the Azores Islands is negative and statistically significant.

Table 6. Mean surface O₃ for NAO > +0.5 and NAO < −0.5 for each season in the period 1988–2009 with the corresponding standard deviation of the mean. The third column shows the confidence level for the difference between the means.

	A NAO > +0.5	B NAO < −0.5	Confidence Level
Winter	42.9 ± 0.3 (<i>n</i> = 605)	45.2 ± 0.3 (<i>n</i> = 349)	100.0 %
Spring	51.4 ± 0.5 (<i>n</i> = 440)	53.9 ± 0.6 (<i>n</i> = 362)	99.9 %
Summer	44 ± 0.7 (<i>n</i> = 366)	46.3 ± 0.6 (<i>n</i> = 456)	98.8 %
Autumn	40.3 ± 0.3 (<i>n</i> = 368)	40.8 ± 0.3 (<i>n</i> = 537)	76.2 %

Sprenger and Wernli (2003) found that there is a strong relationship between the negative phase of NAO and cyclone frequency across the North Atlantic, and specifically that during the negative phase of NAO the low tropospheric destination of the deep STT extends over a large region of the North Atlantic below the 40° N parallel, covering the Canary Islands. Nieto et al. (2000) reported that during positive NAO years, a high occurrence of COLs is detected for all the longitudes from 70° N to about 44° N, while during negative NAO years this high density of COLs is detected on a band from 60° N to 35° N over the North Atlantic, so shifted southwards and, consequently, most likely to influence the subtropical region of the North Atlantic.

Creilson et al. (2003), using TOR data, found that the latitude band of greatest tropospheric O₃ was in the central mid-latitudes (35–40° N) and not the upper latitudes (40–45° N). In Fig. 15 we have plotted the averaged TOR in winter (January–March) and spring (April–June) for years with NAO > +0.5 and for years with NAO < −0.5, as well as the corresponding ozone relative differences between negative and positive NAO phases for each season. It is noteworthy that in winter a negative phase of NAO results in higher tropospheric O₃ amounts over most of the geographical domain of our study, and clearly over the Eastern North Atlantic. These results agree with Pausata et al. (2012), who found an increase of few ppbv of surface O₃ concentrations in stations of the western part of the Iberian peninsula in winter under negative phase of NAO, corresponding to the increase of TOR as can be seen in Fig. 15e. In spring with a negative phase of NAO, there is a significant increment in tropospheric O₃ (~ 10%; 5 Dobson Units) in a band that stretches across the eastern North Atlantic (over the Canaries), North Africa, the western Mediterranean basin, and southern countries of Eastern Europe. The relationship between TOR and NAO breaks down in summer and autumn when the westerlies are not so strong (Creilson et al., 2003).

These results are confirmed by our analysis using surface O₃ at IZO (Table 6). In years with NAO < −0.5 surface O₃ is systematically higher than in years with NAO > +0.5 in

all seasons. However, the highest differences between the two phases of NAO are observed in spring (~ 3 ppbv), and the lowest in autumn (~ 1 ppbv). The confidence level of O₃ differences is higher than 99 % for winter and spring. We can see in Fig. 16 that a significant change in air mass frequencies after 1996 is observed. For example, a considerable reduction in frequency of African air masses associated with O₃ < P25th, and a significant increase in frequency of air masses associated with O₃ > P75th from North America and North Atlantic are registered in winter at IZO. In winters with negative phases of NAO, a more active jet stream and a higher frequency of storms over the North Atlantic within the 30–45° N belt are observed, resulting in a stronger transport west-to-east of potentially polluted air masses from US and major impact of storms over this belt. This is a probable explanation to the sharp increase observed in the O₃ record between 1996 and 1998 (Fig. 3). This is in agreement with the flattening in surface O₃ series observed at European stations since the late 1990s (e.g. Ordóñez et al., 2007; Gilge et al., 2010; Logan et al., 2012).

4 Summary/conclusions

A detailed analysis of a high-quality, long-term (22-yr) surface O₃ time series (1988–2009) at the subtropical high mountain IZO station has been conducted. Diurnal and seasonal O₃ variations have been assessed. Surface O₃ diurnal variations show the lowest values during the afternoon mainly due to an efficient dry deposition on the mountain slopes. The annual mean difference between the daily up-slope and the downslope surface O₃ values ranges from 2 to 5 ppbv. The amplitude and width of the diurnal O₃ “valley” is basically modulated by two factors: the solar radiation, and the consequent heating of the slopes surrounding the observatory, and the synoptic wind strength.

Daily nocturnal (22:00–06:00 UTC) O₃ values have been analyzed for the entire record. The average yearly mean O₃ value at IZO for the 22 yr period is 46.1 ppbv and the peak-to-peak annual cycle amplitude is 15.4 ppbv. There is a slight positive trend in the annual mean (0.19 ± 0.05 % yr^{−1} or 0.09 ppbv yr^{−1}). There is a notable increase in O₃ observed between 1996 and 1998. Seasonal O₃ cycles show a broad maximum beginning in late spring (May), with frequent daily means of 60–70 ppbv. The annual minimum is found in October with O₃ values often falling in the range 30–45 ppbv.

An analysis of the climatology of O₃ pathways using backward trajectories showed that higher O₃ values are associated with air masses travelling above 4 km altitude from North America and the North Atlantic Ocean, while low O₃ is transported from the Saharan CBL, largely corresponding to transport at lower altitudes (< 1500 m a.s.l.).

An extensive review of the potential O₃ production and transport processes into the FT of the North Atlantic subtropical region has been presented, incorporating other

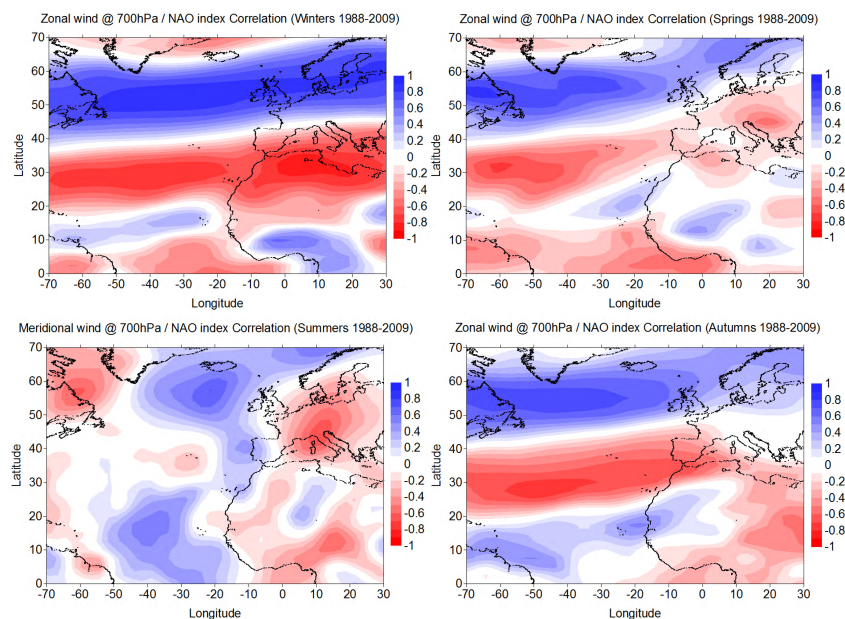

Fig. 14. Correlation between zonal wind component (u) at 700 hPa and NAO-index in winter (JFM), spring (AMJ), summer (JAS) and autumn (OND) for the period 1988–2009.

measurements from the IZO station such as PM₁₀, CO, ⁷Be, ²¹⁰Pb, and additional information from backward trajectories and PV. A clear negative logarithmic relationship was observed between PM₁₀ and surface O₃ for all seasons. A similar relationship was found between O₃ and ²¹⁰Pb.

A positive correlation between O₃ and PV_{max}, and between O₃ and ⁷Be is found throughout the year, indicating that relatively high surface O₃ values at IZO originate from the middle troposphere and in some cases from the upper troposphere. Spatial analyses of PV_{max} show a belt with relatively high values between 45° and 55° N crossing the North Atlantic. In winter and spring this high PV_{max} belt coincides with the corridor where anthropogenic pollution is exported from North America to the North Atlantic. In summer the relatively high PV_{max} values found in the vicinity of the Canary Islands over North Africa are notable. The impact of high ⁷Be events on O₃ values at IZO is considerable; O₃ averages recorded during these events are 7 ppbv and 11 ppbv above climatological values for spring and summer, respectively. Residence time analysis of air masses with daily ⁷Be > 8 mBq m⁻³ (threshold value above which an air mass has stratospheric signature) showed a region around the Canaries extending to the north over North Atlantic in spring and summer. This region coincides with areas where COL developments and STT processes have been reported in previous studies.

The influence of long-range pollution transport events on O₃ levels has been studied using CO data. At IZO a good correlation between O₃ and CO in winter (with an O₃/CO slope of 0.84 ppbv ppbv⁻¹) and in spring, when surface O₃

is within 30–50 ppbv and CO within 85–115 ppbv (with an O₃/CO slope of 0.91 ppbv ppbv⁻¹) is observed. This supports the hypothesis of long-range transport of photochemically generated O₃ from North America. In order to determine the impact of long-range transport of American pollution events, we observed and analyzed, within the period of 2008–2011, those days in which there were at least five consecutive days with a good correlation ($r > 0.75$) between hourly concentrations of O₃ and CO. These events presented the highest O₃/CO ratios (0.53 ± 0.09 ppbv ppbv⁻¹) in spring. In winter this ratio was lower (~ 0.42 ppbv ppbv⁻¹) and agrees quite well with the climatological ratio for this season. The time residence analysis highlights a main contribution from pollution episodes over North America in winter, whereas in spring the origin of the air masses are identified over North America as well over North Atlantic at high altitudes. So, in winter, when the westerlies blow with their maximum intensity, and to a lesser extent in spring, O₃ measured at IZO might be affected by long-range pollution transport from North America.

Differences found between the daily O₃/CO ratios at IZO and seasonal O₃/CO slopes, and between the latter with O₃/CO ratios near the pollution sources could be explained with the following conceptual model based on two processes: (1) O₃ continued to be produced in the plume during its transport in the FT; and (2) contribution from the upper-level air transported downward in the descending dry airstream of cyclones over the North Atlantic, which may have enhanced the lower tropospheric O₃ keeping levels high. This conceptual model conciliates the apparently contradictory re-

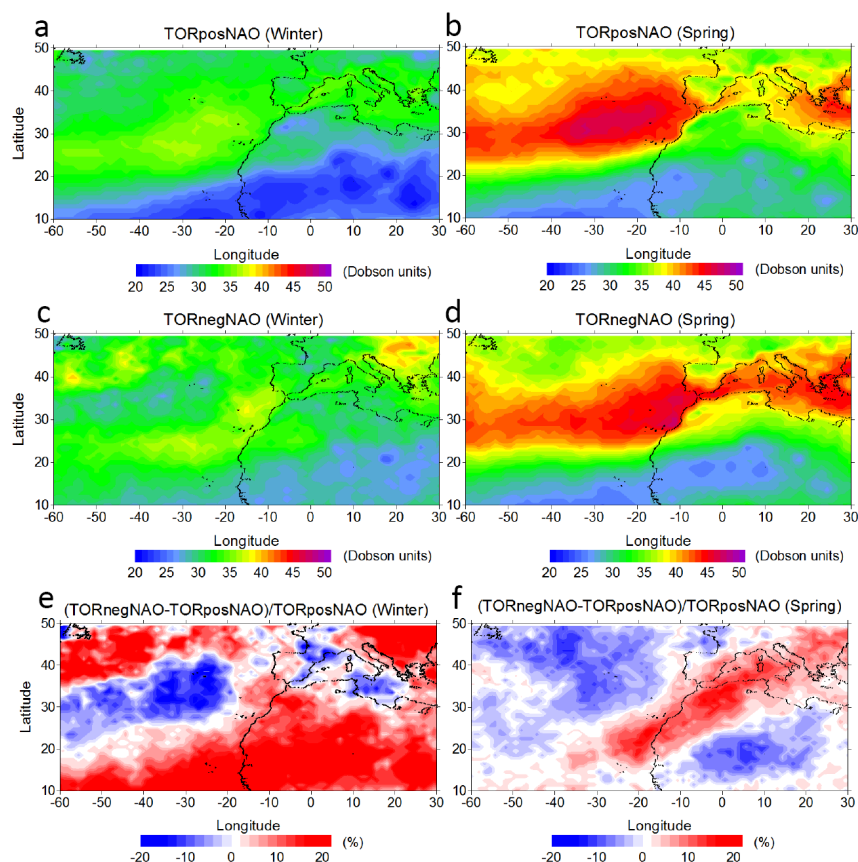

Fig. 15. Averaged tropospheric ozone residual (TOR) data (in Dobson units) in winter (JFM) and spring (AMJ) for years with NAO > +0.5 (a, b) and for years with NAO < −0.5 (c, d). Percentage differences between TOR with negative NAO, and TOR with positive NAO in winter and spring, respectively (e, f).

Fig. 16. Long term frequency of air masses arriving to IZO from Africa sector associated with O₃ < P25th, and from North Atlantic and North America associated with O₃ > P75th in winter. NAO index for winter is also shown.

sults of finding simultaneous positive O₃–CO correlation and positive O₃–PV_{max} and O₃–⁷Be correlations in winter and spring. So, a mixture of photochemical O₃ produced as a result of pollution export from North America and “natural” O₃ from stratospheric intrusions over the North Atlantic into the FT seems to be a likely process. In summer the MCAR plots of O₃ pathways do not show significant transport of O₃ from Europe, and no relationship between O₃ and CO is also found. These results suggest a low probability of occurrence of pollution transport from Europe within the subtropical FT over the North Atlantic. We have analyzed all the episodes in which O₃/CO ratio > 0.75 ppbv ppbv^{−1}. In these cases, 10 % of them in spring and 90 % in summer, O₃ does not correlate with CO (O₃–CO correlation < 0.1).

The residence time analysis of air masses with O₃ > P75th shows two main origins: one located over North Africa and the central Mediterranean Basin, and the other one in a corridor stretching from the Canary Islands to the west of the Iberian Peninsula. These air masses come from altitudes higher than 4 km and show a strong subsidence. All these events are associated with COL or deep-low developments, which indicates they are caused by STT processes.

The geographical origin of these events agree with the PV_{max} distribution over North Africa and the maximum residence time distribution of air masses with ${}^7\text{Be} > 8\text{mBq m}^{-3}$.

Taking into account all O₃–CO relationships found at IZO and in other studies, we propose the following approach concerning the origin of O₃ at IZO. Fresh Pollution O₃ from North America, mainly observed in winter, might be associated with O₃/CO ratios between ~ 0.34 and $\sim 0.4\text{ppbv ppbv}^{-1}$. O₃/CO ratios within ~ 0.40 – $0.55\text{ppbv ppbv}^{-1}$ range likely correspond to aged air masses originated in North America and North Atlantic, in winter, spring and autumn. Aged air masses in combination with inputs from the upper troposphere observed in spring, summer and autumn might be identified by O₃/CO ratios from ~ 0.55 to $0.62\text{ppbv ppbv}^{-1}$. In summer time high O₃ values are associated with O₃/CO ratios $> 0.65\text{ppbv ppbv}^{-1}$, normally the result of STT processes in regions neighbouring the Canary Islands (North Africa, and the corridor extending from Great Britain to the Canaries).

To summarize, tropospheric O₃ recorded in the subtropical North Atlantic is the result of the interaction between transport of photochemical produced O₃ within the North American CBL, the in situ photochemical O₃ produced within the FT during its transport over the North Atlantic, and the “natural” O₃ intrusions from the lower stratosphere over the North Atlantic and North Africa. However, we cannot discern the relative contribution of each main source quantitatively. For this, further studies are needed which might be supported with photochemical model simulations.

Finally, the role played by the NAO in the O₃ content over the North Atlantic, and specifically at IZO has been analyzed. The predominant high positive phase of NAO changes appreciably from 1995–1996. Since this date the NAO alternates between negative or neutral phases and positive phases. This change in the pattern of atmospheric circulation over the North Atlantic results in an increased flow of the westerlies in the mid-latitude and subtropical North Atlantic, thus favouring the transport of O₃ and its precursors from North America, and a higher frequency of storms over North Atlantic, with a likely higher incidence of STT exchange processes in mid latitudes. This resulted in an increase of tropospheric O₃ in the subtropical North Atlantic region after 1996 that has been reflected in surface O₃ records at IZO.

Averaged TOR data in winter for years with NAO < -0.5 shows higher tropospheric O₃ amounts on most of our study region, and clearly in the eastern North Atlantic compared to years with NAO $> +0.5$. In spring there is a significant increase in tropospheric O₃ in a band that stretches across the eastern North Atlantic (over the Canaries), North Africa, the western Mediterranean basin, and southern countries of Eastern Europe in years with negative phase of NAO. These results are confirmed by surface O₃ at IZO. Years with NAO < -0.5 show surface O₃ values systematically higher than those for years with NAO $> +0.5$. The highest differences between the two phases of NAO are observed in spring

($\sim 3\text{ppbv}$), and the lowest in autumn ($\sim 1\text{ppbv}$). This is an important issue in O₃ trend analysis since changes in the phase of the NAO could mask changes in emission of O₃ precursors that have occurred in the last twenty years. O₃ trends over the subtropical North Atlantic region must be properly interpreted taking into consideration phases of NAO. There is still considerable uncertainty in the prediction of NAO, but some studies suggest an intensification of the positive phase of NAO in a scenario of global warming (Gillett et al., 2003), which would impact on the content of tropospheric O₃ over the North Atlantic through the atmospheric mechanisms analyzed in this work.

Acknowledgements. This study has been developed within the GAW Programme at the Izaña Atmospheric Research Center, financed by AEMET. We are particularly grateful to the Izaña Observatory staff (www.aemet.izana.org) for carrying out carefully essential routine operations. We appreciate the accurate audits performed by the World Calibration Centre (WCC-Empa) for Surface Ozone, Carbon Monoxide, Methane and Carbon Dioxide, for providing a trustful and creditable O₃ and CO data quality assurance system at the Izaña Observatory. Data of radiotracers were obtained from the AEROCE project (Joseph Prospero as Principal Investigator). The authors would also like to express their gratitude to NOAA-ARL for the provision of the HYSPLIT transport and dispersion model (www.arl.noaa.gov/ready.html) used in this publication. PV data have been obtained from ERA-Interim ECMWF reanalysis. Monthly NAO index data have been obtained from NOAA/CPC. Zonal wind datasets were retrieved from NCEP/NCAR reanalysis. TOR data have been computed from the database available at the NASA site <http://asd-www.larc.nasa.gov/TOR/data.html>. We thank NOAA/ESRL, Federal Environment Agency Germany, EMPA, and Federal Environment Agency Austria for the surface ozone measurements carried out at Mauna Loa, Zugspitze-Schneefernerhaus, Jungfraujoch, and Sonnblick, respectively. Ozone data have been downloaded from the World Data Centre for Greenhouse Gases (WDCGG; <http://ds.data.jma.go.jp/gmd/wdcgg/>), which is also acknowledged.
